This links to the second problem with fatigue, which is that the physical manifestations of fatigue (generally identified as sleepiness) are difficult to detect without the use of invasive, high-tech, and resource-intensive measures, such as electroencephalography (EEG) or pupillometry. Identifying fatigue as a contributory factor after a crash is also difficult. Fatigue is seldom recorded as a contributory factor in road crash reports, unless it is very clearly evidenced in the crash forensics, or strongly suspected by the investigating officer. Such cases are rare and while there may be localized reports produced from police crash investigations, there are no published articles on sleep-at-the wheel crashes from which we can accurately determine the incidence of crashes caused by drivers actually falling asleep.

Falling asleep is, of course the most extreme outcome of fatigue and presents the highest risk in terms of crash and injury. Crashes caused by sleeping drivers tend to involve single vehicles drifting either off the road, or into oncoming vehicles; both likely to end in head-on crashes with high severity injuries. But the physical consequences of fatigue that lead up to sleep are also a concern. Even low levels of drowsiness cause drivers to pay less attention, to make errors in their judgment (for example of other vehicles position and speeds); and to miss key information and hazards.

Given the range of physical responses to fatigue, and the difficulty in identifying fatigue scientifically—or in identifying a critical point at which normal tiredness becomes something more dangerous—it is unlikely that fatigue as an element of fitness to drive (or to pilot an airplane for that matter) can easily be operationalized. One legal proxy currently utilized for fatigue is number of hours driven (or flown). This is finding its way into some traffic legislation across the world, and there are already restrictions on the number of hours that pilots can fly (in Europe this is currently 11 hours in one shift). In road transport however, it is difficult for traffic enforcement officials to enforce the number of hours a driver has been driving and it is often impossible to use it as a basis for prosecution. “Maggie’s law” (New Jersey, US) was the first piece of legislation to be passed to actively facilitate the prosecution of fatigued drivers involved in crashes. Under this law, a sleep-deprived driver can be certified as “reckless” and can subsequently be convicted of vehicular homicide. Maggie’s law was based on scientific evidence that sleep deprivation has direct and measurable effects of a driver’s competence (Arnedt et al., 2001; Rupp et al., 2007). This research had demonstrated that being awake for 18 hours produces impairment equivalent to a blood alcohol concentration (BAC) of 0.05%. At 24 hours the equivalence is around 0.1%, meaning that severely fatigued drivers who remain awake are potentially even less competent on the road than drivers who are legally drunk. Those drivers who fall asleep at the wheel face the highest risks of all.

The relationship between hours awake and safety performance is not as simple as it may seem, however, and the effect of fatigue on the performance of drivers is not identical in all drivers. In fact some research suggests that our brains have an extraordinary ability (when fatigued) to compensate for diminished cognitive functioning, allowing us to maintain adequate levels of performance under non-challenging driving environments (Philip et al., 2005). As a result, most drivers feel confident when driving tired; their brains have found a way to maintain a degree of cognitive competence. We don’t fully know how brains achieve this—we do, however, know that this competence is temporary and unreliable, as evidenced in high numbers of fatigue related crashes.

The scale of the actual problem of fatigue is hard to ascertain. Crashes resulting from fatigue and sleeping drivers are the tip of the iceberg, as many more near crashes occur which are never documented. Possibly the closest approximation of the extent of the problem in driving comes from research into drivers’ past experiences. Surveys of drivers from across multiple countries confirm that around half of drivers will admit to having driven while drowsy, and that frighteningly high levels (between 13% and 37%, depending on source) admit to having fallen asleep at the wheel. These numbers tend to be higher for males, and highest in the population of heavy goods vehicle drivers.

The significance of Maggie’s law was not that it conclusively defined fatigue, but that it was the first legislation of its kind to enable the prosecution of a driver for reckless driving, specifically for driving while knowingly fatigued. The fact that only one other state in the United States has adopted this legislation is possibly indicative of the difficulties that remain with proving fatigue; that is, proving the link between lack of sleep and performance impairment. This illustrates the importance of finding a measurable aspect of fatigue to eliminate fatigued drivers from the roads and therefore reduce crashes.

Defining Fatigue

Various researchers have defined fatigue; however, there is no consensus view and many definitions highlight the multidimensionality of fatigue as a construct. Elements commonly addressed include an overwhelming exhaustion, a lack of energy, a feeling of imminent sleepiness, and poorer physical and cognitive functioning. These concepts are helpful in conveying a shared understanding of the term but less useful when it comes to developing a watertight definition for prosecution purposes.

Causes of Fatigue

Complex in definition, fatigue is also complex in origin. It has many underlying potential causes and the interaction between contributory causes is also complex. The main causes are:

Sleep deprivation: This can be summarized succinctly as an insufficient amount of quality sleep over a sustained period. Different individuals require different amounts of sleep, but under this definition sleep deprivation emerges when a person has not had seven hours of sleep for two consecutive nights, or when that sleep has been fragmented, restricted or interrupted. The longer a person goes with less than average sleep per night, the faster sleep deprivation accumulates. Sleep deprivation has been shown to have a significant impact on cognitive functions of the brain including alertness, perceptual skills, reaction times, psychomotor coordination, judgment, decision making and risk propensity (Curcio et al., 2001; Lim and Dinges, 2008).

Circadian rhythm: All living organisms are subject to daily routines, which affect the amount of energy they are able to expend on tasks. This is known as circadian rhythm, and in humans the hormone responsible for circadian rhythm is melatonin, which is manufactured in the pineal gland. As melatonin levels increase, alertness and information-processing functions of the brain drop. There are typically two periods each 24 hours in which melatonin levels peak—for the average person these are between midnight and 6:00 a.m., and then again between 2:00 and 4:00 p.m. Of course age, gender, and sleeping routine can influence this (so, e.g., people working night shifts will experience different lows). These periods of lower cognitive functioning coincide with feelings of fatigue, and with reduced ability to operate machinery and to cope with the demands of complex tasks, such as driving. It is not a coincidence that fatal crash numbers are disproportionately high during the period of midnight to 6:00 a.m. (when normalized against traffic volumes).

Chronic sleep disorders: These include medical conditions, such as obstructive sleep apnea, restless leg syndrome (RLS), narcolepsy and chronic fatigue syndrome. All of these conditions undermine levels of alertness and physical and cognitive function, though to different degrees. While many people across the world suffer from such conditions, a key problem associated with chronic sleep disorders is that they can often go undiagnosed; with drivers being largely unaware that their sleep patterns may result in them driving fatigued. For example, meta-analyses of studies in the United States and Europe suggest that around 20% of adults suffer some degree of sleep apnea, with only 5% being formally diagnosed and undergoing treatment. Significantly fewer people (e.g., estimated at 0.05% of the US citizens) suffer from narcolepsy, with only a fraction of these receiving the treatment. Though a less common condition, sufferers of narcolepsy are particularly at risk of crashing as they are subject to periods of overwhelming sleepiness throughout the day.

Length of drive, and high demand conditions: Research into the relationship between work effort and fatigue has concluded that the degree of fatigue experienced is directly proportionate to the length of a task performed. Sustained task performance is related to performance decrements. Essentially, the longer a task is performed, the worse it is carried out, a fact that has been confirmed in both laboratory studies and also among drivers in real driving conditions.

When a task involves continuous cognitive engagement—that is, when the task is difficult or requires especially high levels of attention, fatigue will emerge at a faster rate than under low demand conditions. On the other hand, monotonous driving environments pose their own risks for drivers as they can induce a feeling of sleepiness simply because the driver's brain is not sufficiently engaged with the task. A road with a low flow density and a monotonous road environment can cause depreciation in alertness and driver vigilance (Thiffault and Bergeron, 2003).

Medication and drugs: The use of some antibiotics, antidepressants, and antihistamines can cause drowsiness and attention deficits in drivers. While these side effects are clearly stated on the medication inserts, not all drivers may be aware of these before they take them. Illegal drugs and alcohol also affect cognitive function. Alcohol in particular has depressive attributes, which affect awareness as well as reaction times.

Shift schedule: Professional drivers are one of the groups of people who are more likely to be affected by fatigue; especially when their employment requires shift driving at different times of the day. A science of shift schedules has emerged in recent years, which minimizes the impact of shift changes on circadian rhythm, and allows a driver's body time to adjust to new time demands. Shift schedules are applied in many industries such as the mining and medical industries, as well as (increasingly) in the transportation sector.

Drivers Most Susceptible to Fatigue

A few groups of drivers are more susceptible to fatigue than others. They include:

- Professional drivers—not only during their driving shifts, but also driving home at the end of the shift.
- Drivers who work varying shift patterns.
- People who work more than 72 hours a week.
- Drivers who drive at times when their circadian rhythm suggests they should be resting
- Long distance drivers, especially where insufficient rest stops have been taken.

Diagnosing Fatigue

Post-crash: Fatigue is often designated a contributory factor in crashes only when other factors have been eliminated. In fatal crashes, for example, fatigued drivers are commonly identified only by a lack of evidence of other causal factors, as well as no indication that evasive action had been taken by the driver. The underlying reason here is that fatigued drivers lose the ability to respond appropriately to unexpected events.

Pre-crash: In international legislation (where it exists) fatigue is most often defined simply on the basis of time without sleep, or the time elapsed since the last rest period. This is a pragmatic approach to some of the difficulties associated with physical identification of fatigue on the basis of physiological symptoms (e.g., changes in eye movement, heart rate, and so on). There are a number of scientific techniques available for conducting such analysis but they tend to be reliant on technology and on expensive equipment. Also, some measures available to accurately detect fatigue depend on prior knowledge of a driver's physiology in a non-fatigued state (e.g., heart rate changes requires an understanding of the baseline heart rate for that person before fatigue). This is clearly impossible in most roadside investigations.

Fatigue measuring techniques that have been developed for laboratory conditions include:

- **Percentage of eye closure (PERCLOS):** The PERCLOS technique calculates the percentage of time in a minute that eyelids are closed. According to the US Federal Highway Administration (FHWA) and US Highway Traffic Safety Administration (NHTSA), this is regarded as the most promising driver fatigue detecting technique (Singh et al., 2011).
- **Ocular parameters:** Measuring the characteristics of eye movement and pupil constriction.
- **Heart rate variability (HRV):** The use of HRV can serve as an early fatigue indicator. The HRV increases exponentially with increasing fatigue levels.

- Neurological parameters: Changes in oscillatory brain activity occur with fatigue, and can be used to identify mental fatigue.
- Head movements: Head nodding is the last cue before the occurrence of micro-sleeps and the onset of sleep. This measurable aspect is an efficient approach to determine fatigue. Unfortunately, it is the last cue providing an indication that the driver is falling asleep and might have been unfit to drive.

Assessing fatigue in real driving environments is more challenging, given the constraints of time, space, specialist staff, and budget limitations. There are numerous devices that have been developed for experimental use but these are not yet commercially available. One such device is the psychomotor vigilance test (PVT), which uses the reaction time of a driver to determine his/her level of alertness. Reaction times are arguably the most important aspect of driver performance when it comes to crash avoidance. They can be measured on palmtop machines with little in the way of supporting computer backup.

A second method, which avoids technology altogether, is a self-assessment test carried out by drivers. Many instruments have been developed over the years to allow drivers to record their experiences—of them the Swedish Occupational Fatigue Index (SOFI) stands out as a sound way of measuring fatigue among professional drivers. This technique incorporates multiple dimensions of fatigue, including physical, cognitive, and emotional fatigue, grounded in a test that can be customized to the demands to the task—in this case the driving environment.

A third method of assessing fatigue is the tachograph—a control device that records journey data of a vehicle. This technique, unlike the two mentioned above, does not attempt to measure the impact of the task on the driver, but makes a fairly simplistic assumption that the performance of the driver is directly related to the amount of time spent driving. It disregards any other external factors that could have an influence on the driver. The tachograph presents driving time as a proxy for fatigue. While this is a crude measure, it has the advantage of being consistent and for allowing legislation to be developed which similarly defines fatigue simply in terms of hours spent driving.

Preventing Fatigue

Enforcement

Fatigue in international legislation:

The manner in which traffic officials manage fatigued drivers is dependent on whether fatigue is defined in the law, the clarity of that definition, and the punishment that is consequently indicated. Where any of these elements is unclear, successful prosecution of drivers for fatigued driving is unlikely, and seldom attempted. Of course many countries have legislation that enables a wide range of generic forms of dangerous driving to be prosecuted, but because of the many difficulties associated with identifying fatigue as a definite cause, fatigue itself is seldom prosecuted under such laws.

Fatigue related legislation does exist in a small number of countries, and examples from the United States, Europe, and Australia are summarized below.

The United States

Maggie's law, New Jersey, which was passed in 2003, expanded the state's prior definition of a reckless driver to include fatigue. In this case, fatigue is defined simply in terms of time without sleep (defined as having had no sleep for 24 hours). Under this law, a driver who causes a fatal crash due to fatigue can be prosecuted for vehicular homicide. No performance-related impairments need to be proven; no physical indicators of fatigue are examined. This is a positive step forward in that fatigue is recognized as being detrimental to driving and a significant contributor toward recklessness on the roads. However, the take-up of the model has been low. Other states within the United States generally believe that there is sufficient provision in their legislation for fatigued drivers to be prosecuted (e.g., under their definitions of reckless driving and vehicle homicide laws). The fact that fatigued driving in the United States does not appear to be declining suggests that the legislation that does exist is not effective.

European Agreement (AETR)

The European Union has a number of restrictions on driving hours for drivers of goods or public transport vehicles, encapsulated in Articles 6 and 7 of the Regulation of the European Parliament and of the Council No 561/2006. The basics include the following requirements: A daily maximum driving time of 9 hours and weekly maximum of 56 hours is mandated. In addition, cumulative driving time over 2 weeks should not exceed 90 hours. Breaks should be taken after 4.5 hours, and should last no less than 45 minutes.

Driving crews crossing international borders are subject to a further Agreement, namely the European Agreement Concerning the Work of Crews of Vehicles Engaged in International Road Transport. The definitions for driving time, breaks, and rest periods as stipulated by the Agreement are similar to those defined earlier, but an additional stipulation regarding record keeping is included. This says:

. . . 6. This record (of driving) shall be entered either manually on a record sheet or printout or by use of the manual input facilities of the recording equipment. (Regulation (EC) No 561/2006 of AETR Art 6 & 7)

When records or driving time are required by law, a recording (control) device becomes necessary. Most countries in Europe use tachographs for this purpose.

United Kingdom

Drivers of public or goods vehicles in the United Kingdom are subject to the conditions laid out in the EU regulations. However, and additional requirement in the UK is the recording of time driven, even when driving within the boundaries of the UK itself. Here the primary fatigue management approach is to require Passenger Carrying and Goods Vehicles to have a control device installed. The relevant extract from UK legislation is Extract V—Part II Art 97 Installation and operation of recording equipment in vehicles, which reads as follows:

Subject to the provisions of this section, no driver shall drive a vehicle to which this Part of this Act applies unless-

There is installed in the vehicle in the prescribed place and manner equipment for recording information as to the use of the vehicle, being equipment of such type or design as may be prescribed or approved by the Minister for the purposes of this section; and

That equipment is in working order. (Transport Act 1988 Art 97)

The driver is required to be able to produce a work and rest record for the previous 28 days.

Australia

Australia is one of the more advanced countries regarding fatigue management for heavy goods vehicles. In February 2014, national legislation changed to facilitate a single regulation for the whole of Australia, namely the National Heavy Vehicle Regulator (NHVR). With this legislation, the responsibility for fatigue management of these now falls under the national authority and not the regional authority as in the preceding years. NHVR is valid for all vehicles with gross vehicle mass (GVM) over 12 tons and buses over 4.5 tons carrying more than 12 adults.

The NHVR addresses prescribed work and rest schedules, vehicle standards, maximum permissible mass and dimensions, and restraining of loads on heavy vehicles.

Fatigue is monitored by officials checking if drivers or employers are adhering to the work and rest requirements as prescribed by the legislation, depending on the type of accreditation of the driver. This is done through a requirement that each driver keep a work diary of previous shifts worked, recorded in a logbook.

A policy of fatigue management is managed nationally through the application of a policy of advanced fatigue management that applies a risk classification system (RCS) to drivers based drive/rest profiles of different drivers. This is applied to fleet drivers and heavy goods vehicle drivers only. This system works on identifying high-risk schedules by analyzing the combination of work and rest times and allocating countermeasures to mitigate the proposed risk. Each driver is required to evaluate the risk of his/her work and rest schedule by completing a standard RSC matrix.

Drivers and or employers can receive penalties and demerit points for not adhering to the requirements, failing to provide correct documentation or falsifying work and rest records. The police or enforcement officers determine the severity of the offence and the magnitude of fine; however, a maximum value is defined in the NHVR legislation itself. Drivers can receive driver's license demerits points when breaching work and rest schedules requirements.

Educational Initiatives

As with most risky driving behavior, prevention appears to be better than cure. With fatigue, however, few efforts internationally have been assessed in terms of educating drivers about the need to avoid fatigued driving; for example, publicizing the risks of driving during the circadian low periods, or even the need to take rest breaks while driving. A review of road safety campaigns across a number of countries showed very few interventions of this nature (Hashemi Nazari et al., 2017). More common are interventions aimed at addressing fatigue once it has already emerged. Interventions with fatigued drivers in Australia and Israel, for example, involved encouraging drivers to talk to passengers, to listen to the radio, open a window or wash their face. Drivers in an intervention in the Netherlands were encouraged to drink a caffeinated drink, or to stop their car and sleep for a short while. In fact, only sleep itself has proven to be a reliable antidote for fatigue, and it is unclear what effects other interventions have had—a systematic review carried out in 2017 or myriad interventions found that precise improvements in the degree of sleepiness were uncalculated and indeed uncertain.

Engineering Responses

The problem of fatigue cannot be dealt with by enforcement and education alone. Traffic engineers are important role-players in this regard and have multiple contributions to make, not least in developing new and effective ways of increasing driver alertness (surface treatments, such as rumble strips, interactive road signage, etc.), providing rest areas for fatigued drivers and implementing a policy of protective (e.g., center barriers on 2-lane roads to prevent head-on collisions) or forgiving road design (so that when crashes do occur, damage to the vehicle occupants is minimized). Vehicle designers possibly play the biggest role in both identifying fatigue in a driver and mitigating it—new vehicle technologies are emerging to prevent crashes by waking a driver who is falling asleep and even engaging emergency braking features before a crash occurs.

The biggest problem with fatigue lies in the difficulty we have to identify and operationalize it, and the consequent lack of public discourse there is about fatigue as a factor in road safety. More work is needed urgently on fatigue to increase public awareness as a first priority. While fatigue can and must be reduced, it is likely never going to be removed completely as a threat.

Speed Governors and Limiters

Excessive speed is one of the main road safety problems according to many experts; and authorities in most parts of the world claim that excessive speed, that is, speed above the prevailing speed limit, is a strongly contributing factor to many crashes and—particularly—to fatal crashes and crashes with severe injuries. In the United States, the Federal Highway Administration (FHWA) states that “Speeding, traveling too fast for conditions or in excess of the posted speed limits—is a factor in almost one-third of all fatal crashes.” They continue, “Although much of the public concern about speeding has been focused on high-speed Interstates, nearly half of speeding-related fatalities occur on lower speed collector and local roads” (FHWA, 2019). In the EU, the problem is of the same magnitude: “500 people die every week on EU roads, a figure that has refused to budge for several years. And driving too fast is still the number one killer” (ETSC, 2019). And, the World Health Organization (WHO) has concluded that, in high-income countries, speed contributes to about 30% of road deaths, while in some low- and middle-income countries speed is the main factor in about half of road deaths (WHO, 2019).

The role of speed as a killer of people has been noted for almost as long as there have been vehicles on our roads. The way the problem has been tackled has been almost in vain, probably because speed is at the same time one of the most attractive characteristics of automobiles. Mobility in terms of “good speed performance” has obviously been valued so highly that controlling speed has not had any high priority at all. Therefore, even if there have been many efforts to reduce speeds, almost all of them have been without any real success. It is rather so that these efforts have the aim of demonstrating the will to do something without taking any political risks. Billions of US dollars are spent every year in order to try and convince drivers to drive slower/keep to the speed limit. This kind of information and education does not produce any disharmony to drivers. When they see the message, they can just think “yes, that sounds good, and it is good that authorities bother,” without being forced to follow it themselves. The result is discouraging regarding speed: speed campaigns have a very small effect. Meta-analysis has shown that while drinking and driving campaigns have the effect of an 18% reduction in all accidents, speed campaigns only have an effect of 4%. Besides, it seems as if the effect of the campaign goes down over time. In the 1980s, the overall effect was a 16% reduction in accidents, but it came down to 5% in 2000–10 (Høye et al., 2014). So, the conclusion regarding campaigns is that they are conditional on other speed reduction measures, such as speed enforcement and the acceptance of legal changes. On its own, the effect of campaigns in changing actual speed behavior is likely to be limited. It seems generally as if efforts have been quite small, and the problem of speeding does not seem to be solved. In Sweden, one of the countries leading the safety rankings, the conclusion is that speed development has not been positive during at least 15 years, in spite of very straightforward goals regarding speeds. The same goes for the whole of EU with its 28 countries. It is concluded that speeding remains a significant problem in most if not all European countries. On urban roads, where 37% of all EU road deaths occur, researchers found that between 35% and 75% of vehicle speed observations were higher than the legal speed. On rural non-motorway roads, where 55% of all road deaths in the EU occur, between 9% and 63% of vehicle speed observations were higher than the speed limit, while on motorways, where 8% of all road deaths occur, between 23% and 59% of observed vehicle speeds were higher than the speed limit (ETSC, 2019).

Global results indicate a similar problem. Of the 175 countries participating in the Global Status Report, 123 have road traffic laws that meet best practice for one or more key risk factors. During this review period, 10 additional countries (45 in total) have aligned with best practice on drink-driving legislation, 5 additional countries (49 in total) on motorcycle helmet use, 4 additional countries (33 in total) have aligned with best practice on the use of child restraint systems, and 3 additional countries (105 in total) on the use of seat belts. Less progress has been made on adopting best practice on speed limits, despite the importance of speed as a major cause of death and serious injury (WHO, 2018).

Speed is simply a major factor in overall road safety performance. It becomes obvious that authorities need to be more proactive and decisive regarding what types of measures are warranted. Soft measures such as education and campaigns are not at all sufficient. What is needed is hard measures, measures that are decided by decision-makers, passed into law, forcing drivers to comply. There are primarily two candidates that fulfill the criterion. They have documented effects on safety and a great potential of solving safety problems in a more general way. The problem is that they are still not implemented in a significant way, most probably because there is hesitation among politicians and other decision-makers in agencies. The two candidates are given in sections “Speed Enforcement, Particularly Camera Enforcement” and “Speed Governor.”

Speed Enforcement, Particularly Camera Enforcement

Drivers respond to a measure that will lead to fines and even harder consequences if you are not keeping the speed limit. The problem, however, is that there is still a lot of speeding, for many reasons: drivers know that there is enforcement, but those who really want to drive faster can inform themselves thanks to different apps that can provide them with information on where the enforcement is taking place. This is particularly true for camera enforcement, where the cameras are stationary. Besides, in most countries, the number of cameras is too small to be able to cover a large road network. There is an opening that should change the scope considerably and make camera enforcement much more effective. The measure is area control, that is, two cameras are linked and the average speed is calculated. This is now used in Norway, particularly in tunnels where the speed can be quite high. The longest is 22 km and forcing drivers to keep the speed limit all through the tunnel. Besides, when it becomes more common to connect adjacent cameras that are located a few kilometers or more apart, drivers will feel less safe that there is no enforcement on place wherever they are driving at any given time. An alternative to using cameras would be to use GPS and fine people, for example, \$1 per kilometer for each kilometer per hour they speed. Rather than having a low probability of getting a high fine, there would be a certainty of getting fined when speeding. An habitually speeding driver, driving 10,000 km per year with an average speed 10 km/h above the limit, would then have to pay \$100,000 in fines per year, whereas someone who was speeding by 10 km/h just once while passing a vehicle over a distance of 200 m would only have to pay \$2, and maybe the first \$100 per year would be forgiven. One drawback with such a system would be that it would seem costly to low-income individuals but affordable to upper-income people unless the fine is dependent on income. That certainly could be the case since it already is for criminal speeding in Scandinavian countries.

Speed Governor

A *speed limiter* is a governor used to limit the top speed of a vehicle. Today, modern motor vehicles most often have a speed performance capability that means a maximum speed of at least 200–250 km/h and an acceleration of 0–100 km/h in about 5–10 s. Even though, with higher demands on environmental aspects, car manufacturers are promoting their cars with arguments as “the driving pleasure” and speed and acceleration performance. They even claim that overtaking maneuvers are safer thanks to better performance. The impact of this promotion is quite big. As of 2006, total advertisement spending by the automotive sector amounted to over 20 billion dollars, 40% of which benefited the printed press (Beattie et al., 2017).

The problem is that there is no verification empirically regarding this development without any demands to assess the consequences regarding effects on speeds and safety.

In view of the slow progress regarding speed, a system that sees to it that the driver cannot drive faster than the prevailing speed limit should of course have a great theoretical potential. Figures from different countries and regions state that if everybody always kept the speed limit, then the number of fatalities would drop by anywhere between 21% and 55%. Thus, the potential is extremely high, but still the interest among drivers, authorities, and industry has been very limited. Almost all actors claim that there is no need for this “dramatic” and “non-popular” measure, because there is an ever-going development of new and more effective measures. They then refer to new both passive and active safety measures like crash-worthiness and new IT systems like autonomous emergency braking (AEB), automatic driving. These systems may have quite good effects individually; however, from a speed point of view, it does not solve the general problem with speeding. There is even the obvious risk that this kind of measure makes the driver more comfortable relying on these new systems. But, again, nobody has warranted an assessment of the present situation. How do all these new systems work from a speed point of view? Generally, research around the relation between vehicle performance—speed and acceleration—has not been given any priority neither by industry nor by governments. There are only a few studies. Those few examples that exist indicate primarily negative safety effects. In an analysis by Høyen et al. (2014) only five relevant studies were identified. Four of them indicate significant increase of accidents with increasing power.

Speed governors in private vehicles do exist already, but only in a very special setting. In Germany, the car industries themselves have agreed on a Speed Governor in their cars, set to 250 km/h. However, since Italian-made cars can go faster, Mercedes-Benz and BMW now also allow customers to get their cars without this limiter. Neither the German government nor the European Union seems to have been involved, and the outcome has not been assessed either. It is hard to believe that it would have any implications on driving and driving speeds away from German Autobahns. In March 2019, Volvo announced that it would be limiting the top speed on all of its vehicles, worldwide, to 180 km/h in a bid to reduce traffic fatalities. The new speed limit will be implemented on all model year 2021 cars. Also, European Citroën, BMW, Mercedes-Benz, Peugeot, Renault, Tesla, as well as some Ford and Nissan cars have driver-controlled speed limiters fitted or available as an optional accessory that can be set by the driver to any desired speed. The limiter can be overridden if required by pressing hard on the accelerator. So, they help drivers keep the posted speed but certainly do not guarantee that they do.

What is more relevant from a safety point of view is that true speed governors already exist in many countries in many vehicles. Authorities have introduced governors in many jurisdictions controlling the maximum speed of heavy vehicles and buses. It is not introduced in far from all countries, and the interest is not always great. Like in India, where the Transport Minister Nitin Gadkari has said that he will “soon demolish the governor system meant for commercial vehicles as limiting speed had no role in tackling the rising number of fatalities and accidents on the roads” (Pankaj Doval/TNN/September 6, 2018). Besides, these Governors that exist are often set on plus 10 km/h in relation to the highest prevailing speed limit for those vehicles. This means that it is still possible to

exceed the speed limit on all roads, especially on roads with lower speed limit than the maximum. The result is, therefore, very limited effects in total (Vaa et al., 2012) even if all vehicles are so equipped. In North America, Ontario and Quebec, both in Canada, are the only two jurisdictions to mandate speed limiter technology. It is set at 105 km/h on all trucks operating in those provinces even though the highest speed limit allowed in either province is 100 km/h for trucks as well as for cars. In most of the EU, heavy trucks have speed limiters allowing up to 90 km/h speed even on secondary roads where speed limits are much lower.

So far, every attempt to control the speed of the vehicle has stranded on the question of mandatory use. Therefore, the terms Speed Governor or Speed Limiter are abandoned. Instead, there is now one concept only, called intelligent speed adaptation (ISA), which includes all sorts of speed adaptation concepts. ISA is the general term for advanced systems in which the vehicle knows the speed limit at any given location and is capable of using that information to give feedback to the driver. ISA is a measure where the driver is assisted in keeping the speed limit by some kind of signal, auditory, visually, or haptic (resistance in the gas pedal). ISA can be operated in many different ways. The main point is that the use so far has been voluntary; you can always override the system, in one way or another. Today, ISA has been introduced in many car models, but again the driver always decides whether the system should be in operation or not.

An ISA that is a Speed Governor, that is, limiting speed to the prevailing speed limit, has never been tried by any of the car industries, as far as we know. In the 1980s and onward, there have, however, been a number of authority-driven, empirical trials of ISA with various degrees of demands regarding speed compliance, from Speed Governor type to various other solutions with different degree of voluntary use.

In France, the earliest study was that of Malaterre and Saad (1984) who tested vehicles equipped with two different ISA systems. The first system (System A) comprised a control panel placed near the steering wheel with fixed speed limit controls. Once the vehicle reached the selected speed limit, the accelerator pedal became stiffer, but this hard point could be overridden if necessary. This was the equivalent of a "mandatory" system described earlier. The second system (System B) involved a level, which the driver used to set a given driving speed, beyond which the accelerator pedal had no effect. A kickdown system enabled the vehicle to override the chosen speed for as long as the pedal stayed depressed. Releasing the pedal brought the vehicle back to the chosen speed. This was the equivalent of a voluntary system of speed control. Studies showed how subjects used the two systems, according to the posted speed limit and the chosen driving speed. A comparison between the two systems—system use was imposed and system use on a voluntary basis—showed that the correct speed was much higher in the first case, 72% versus 11% (speed limit: 60 km/h) and 96% versus 42% (speed limit: 90 km/h). The difference is striking.

In Tilburg, the Netherlands, the Dutch Ministry of Transport ran a mandatory ISA field test from 1999 to 2000. A total of 20 passenger cars and a bus were used (information collected from Loon and Duynstee, 2001). The test zone contained 30, 50, and 80 km/h speed limits.

The main conclusions of the Tilburg trial were:

- The ISA system as tested in the Netherlands is technologically feasible; minor improvements are needed.
- As expected, the ISA test in Tilburg has had a positive effect on driving behavior and speed patterns. 95 percentile speeds went from well over speed limit on 30 and 50 km/h roads without the ISA to somewhat under with the ISA.
- The ISA Tilburg test shows that great deal of public support can be gained; adequate communication, however, is essential.

In Eslöv, Sweden, 25 private people driving their own cars got them equipped with speed limiters, automatically activated when the car was inside the built-up area of the city. The trial went on for half a year, in the mid 1990s (Almqvist, 2006). The main results were that average speed for the whole test route for all drivers decreased from 43.5 km/h to 41.5 km/h. The total effect is relatively small (−4.6%), as the speeds were rather moderate in the city even before. Still it represents a theoretical reduction of fatalities by 15%–20%. More importantly, speeding was (of course) gone almost entirely for these 25 people (small technical problems led to some—but minor excessive speeds). The effect of the speed limiter can be clearly seen on major streets where speeds were considerably higher than the allowed 50 km/h, and the longitudinal speeds were strongly harmonized and kept under the speed limit in the after situation (with the speed limiter). Many drivers not having speed limiters also had to slow down.

Behavioral observations showed an improvement in behavior in interactions with other road users, for example, drivers more frequently giving the right of way to pedestrians, cyclists, and other vehicles. The test drivers stated that the Speed Limiter Function should be mandatory. Moreover, it was possible to imagine a mandatory speed assisting system (Speed Governor) for built-up areas.

In 2002, the French Ministry of Transport launched a significant program of experimentation and evaluation in order to better appreciate the effects of the ISA system in terms of acceptance by the drivers and influence on their driving behavior. The two French automotive manufacturers, PSA and Renault, participated with cars in the project (Driscoll et al., 2007). The potential safety benefits of the different versions, based on observed driving speeds, distributions of crash severity, and crash injury risk. Results are given for car frontal and side impacts that together represent 80% of all serious and fatal injuries in France. Of the three system modes tested (advisory, driver select, and mandatory), the results suggest that driver select would most significantly reduce serious injuries and death. The estimate is that 100% utilization of cars equipped with this type of speed adaptation system would decrease injury rates by 6%–16% over existing conditions depending on the type of crash (frontal or side) and road environment considered.

In Leeds, the United Kingdom, an on-road study was carried out, as part of an External Vehicle Speed Control (EVSC) project. A vehicle was equipped with two versions of EVSC, Driver Select and Mandatory. The main findings were:

- The Mandatory system trial in this experiment successfully reduced speeds, particularly in areas where drivers are renowned to being poor at adapting their speed.

- There were no negative behavioral compensation effects. Although drivers were initially unfavorable toward the mandatory system, they reported that driving with the system was safer due to enhanced awareness of potential hazards.
- The effectiveness of the Driver Select system is roughly half that of the mandatory one (Carsten and Fowkes, 2000).
- Prediction based on actual speed changes observed in an ISA project in the United Kingdom is that an ISA system targeted purely at compliance with existing speed limits could, in its strongest variant (i.e., a non-overrideable version), deliver a 29% reduction in injury accidents (Carsten, 2012). Applying the power model of Elvik (2014) translates into a 50% reduction in fatal accidents.

The UK ISA project produced a rich database with high-resolution data on driver behavior covering a comprehensive range of road environment. The field trials provided vital information on driver behavior in the presence of ISA. ISA is predicted to save up to 33% of accidents on urban roads, and to reduce CO₂ emissions by up to 5.8% on 70 mph (112 km/h) roads. In order to investigate the long-term impacts of ISA, two hypothetical deployment scenarios were envisaged covering a 60-year appraisal period. The results indicate that ISA could deliver a very healthy benefit-to-cost ratio, ranging from 3.4 to 7.4, depending on the deployment scenarios. Under both deployment scenarios, ISA has recovered its implementation costs in less than 15 years. It can be concluded that implementation of ISA is clearly justified from a social cost and benefit perspective. Of the two deployment scenarios, the market-driven one is substantially outperformed by the authority-driven one. The benefits of ISA on fuel saving and emission reduction are real but not substantial, in comparison with the benefits on accident reduction; up to 98% of benefits are attributable to accident savings. Indeed, ISA is predicted to lead to a savings of 30% in fatal crashes and 25% in serious crashes over the 60-year period modeled (Carsten, 2012).

The results of all the studies presented clearly indicate that there is a great potential of mandating speed limiters from a behavioral and safety point of view. All trials but the French Lavia project have clearly demonstrated the benefits of an “authority select” mode. And the predicted effect of a reduction of 50% of fatalities—as in the UK project—is verified by the EU-funded and SRA coordinated project PROSPER. The PROSPER project calculated crash reductions for six countries. Reductions in fatalities between 19% and 28%, depending on the country, were predicted in a market-driven scenario. Even higher reductions were predicted for a regulated scenario—between 26% and 50%. Benefits are generally larger on urban roads and are also larger if more intervening forms of ISA are applied (EC.Europa.eu, 2019).

The PROSPER also concluded that benefit-to-cost ratios ranging from 2.0 to 3.5 and from 3.5 to 4.8 were calculated for the two scenarios: market-driven and regulation-driven.

So, the general conclusion is that ISA is demonstrating quite positive results regarding behavior changes, safety changes, benefit-to-cost ratios, and even on climate aspects, even though small in the latter case. The effect of the “authority select” mode (= Speed Governor) is considerably larger in all cases but one. Besides, any possible negative aspects seem to be to a large degree nonexistent in the reported trials.

The main conclusion of these reported trials is that they were ended long ago, and no logical continuation has been following. There has been little effort to follow up the results. There are two lines to follow:

1. Research on how to proceed in order to obtain the theoretical effects of a voluntary—market-driven—concept.
2. How will drivers react once they realize that they cannot go above the speed limit? Behavioral effects, safety outcome? Other effects?

The first line will work as a preparation for line (2). What effort is demanded in order to reach behavioral changes without a mandatory use of ISA?

A breakthrough to get to this is a proposal from the ETSC to mandate speed limiters on all new vehicles sold in Europe has passed a vote by Members of European Parliament in February 2019. If approved for implementation, the technologies would be mandatory for new (not yet designed) models as of May 2022. Existing models (existing cars in production with no significant changes since before 2020) would have to comply by 2024 (NewsGlobe, 2019).

It will use recognition software to read speed limit signs, and, where none are present, GPS data. Drivers will reportedly be able to temporarily override the limit, which will continue to allow highway overtaking. Drivers will receive an audiovisual warning regarding their speed. “If the driver continues to drive above the speed limit for several seconds, the system should sound a warning for a few seconds and display a visual warning until the vehicle is operating at or below the speed limit again,” states the ETSC. The system may allow overriding it too easily to be effective but it certainly is a big step toward mandatory speed governors assuming lobbying does not stop implementation of this.

So far, research progress regarding ISA has been very slow. There are still no major breakthroughs, in spite of 30 years of research on ISA. And in spite of the fact that the speeds can be reduced significantly, and thereby fatalities/injured. Besides, users have been found to have generally positive attitudes and some sections of the public have been shown to be willing to purchase ISA systems (Carsten, 2012). From a survey of a representative sample of British drivers, we learn that “While a non-negligible part of the sample population has such strong opposition to ISA that no reasonable discounts or incentives would lead to them buying or accepting such a system, there is also a large part of the population that, if given the right incentives, would be willing or even keen to equip their vehicle with an ISA device” (Chorlton et al., 2012).

It is important to add to this picture that the car industry does a lot for safety. They have been, and are, extremely successful in improving the crashworthiness of cars. Much of this work has been enhanced thanks to the NCAP program where the industry has been encouraged—and, in practice, forced—to improve the performance. Lately Euro NCAP has introduced speed assistance that could be one important accelerating factor for the implementation of ISA. However, Euro NCAP only promotes installation of

voluntary systems. They assess different functions of Speed Assist systems, informing, warning, or actively preventing. Besides, Speed Assist is one of five systems under the heading Safety Assist. The other four are “Electronic Stability Control,” “Seat-Belt Reminders,” “AEB Interurban,” and “Lane Support.” This means that Speed Assistance only contributes to one fifth of the Safety Assist score. The Euro NCAP approach is of course encouraging. However, the assessment does not guarantee any actual change of speeds. The other included safety systems: AEB, electronic stability control, etc., are automatic systems that work once they are installed in the car. Speed Assist does not work automatically, but presuppose an active step by the driver, that is, to give high priority to a safety device. However, this is what normally not happens. In line with all other systems that are assessed by NCAP, with crash tests, etc., Speed Assist should be assessed based on the actual speed effect, not a fictive one.

So, the conclusion regarding ISA is that there still seems to be great unwillingness among industry and authorities to include Speed Governor on their agenda. It is obvious that the car industry has managed to set the scene, so as to exclude all discussions—and research—on the most promising measure that could prevent all speeding. But, as technical progress is made almost every day, it is going further toward concepts more and more similar to Speed Governor concepts. This is of great importance. A governor like this may change the world of driving entirely.

Biography

Christer Hydén has been active in the traffic safety field for around 40 years. His first achievement was the development of a Traffic Conflict Technique, a way of assessing risk on the roads with the help of near accidents. He was the President of ICTCT (at first standing for “International Co-operation in Traffic Conflict Techniques” and later for “International Co-operation on Theories and Concepts in Traffic Safety”) from 1977 to 2011. Another field of expertise is the impact of speed, and the effect on speed as well as safety of different measures, like traffic calming and speed limiters in vehicles. He is also a member of the Independent Council for Road Safety International (ICORSI).

Glossary

85th percentile speed The speed at or below which 85 of vehicles travel. Speed limits are often established such that they are within 5 mph or 8 km/h of the 85th-percentile speed of free-flowing traffic.

advisory speed Advisory speeds warn drivers to proceed at a speed lower than the speed limit due to geometric, weather, or other conditions.

design speed The design speed is a selected speed used to determine the various geometric design features of the roadway.

differential speed limit A system that prescribes different maximum speed limits for different vehicle types or user groups. This is usually applied as one maximum speed limit for light passenger vehicles, and a lower maximum speed limit for trucks and heavy commercial vehicles.

free-flow conditions Free-flow conditions are characterized by drivers being free to drive at their desired speed and not constrained by the presence of other vehicles or downstream traffic control devices.

operating speed The speed at which vehicles are observed operating during free flow conditions. The 85th percentile of the distribution of observed speeds is the most frequently used measure of the operating speed.

speed limit, posted The posted speed limit is the maximum lawful vehicle speed for a particular location as conveyed to the motorist on a regulatory sign. This is a black-on-white rectangular sign in the United States and a black-on-white or yellow round sign with a red border in countries that have adopted the Vienna Convention. Standard engineering practice is to post speed limits where speed zoning has altered the limit from the statutory value.

speed limits, statutory Numerical speed limits specifically provided for under a country's or state's traffic codes that apply to various classes or categories of roads (e.g., interstates, rural highways, residential streets, etc.) in the absence of posted speed limits.

speed zoning Speed zoning is the process of performing an engineering study and establishing a reasonable and safe speed limit for a section of roadway where the statutory speed limits given in the motor vehicle laws do not fit the road or traffic conditions at a specific location.

speeding The legal definition of speeding is exceeding the posted speed limit, or a statutory speed limit. In the road safety community, speeding is defined as exceeding either of these limits or driving at a speed too fast for conditions.

Introduction

Speed limits inform drivers of the highest speed that is considered safe and reasonable for ideal traffic, road, and weather conditions. As they are established by legislative action, speed limits also provide a basis for the enforcement of unreasonably high travel speeds. Given the political nature of the subject, speed limits have been a longstanding concern of transportation agencies and the subject of numerous research studies.

The extant literature has generally shown that speed limit increases are associated with significant increases in traffic fatalities. The fact that fatalities increase with speed limits is unsurprising given the physics involved, which show the kinetic energy involved in a crash increases with speed. Despite this fact, 25 US states increased their maximum statutory speed limits on rural interstates between 2001 and 2018 as shown in Fig. 1. As of October 2019, there are 18 US states that have a maximum statutory speed limit of 75 mph (120 km/h) or above, including eight states with limits of 80 mph (129 km/h) or above. These and other historical increases have been supported by the fact that existing operating speeds tend to exceed the posted speed limit, often by significant amounts, on

Figure 1 Maximum rural interstate speed limits by state in 2001 and 2018.

high-speed roadways (Fitzpatrick et al., 2003). The maximum speed limit on freeways in most other industrialized countries varies between 110 km/h and 130 km/h (SafetyNet, 2009).

Statutory limits are generally applicable for a particular class of highways with specified design, functional, jurisdictional, and/or location characteristics (FHWA, 2012). These limits are generally higher in driving contexts that are less complex and challenging to navigate, as well as where there is an expectation of higher travel speeds based on the contextual environment, such as rural highways.

Speed limits are typically established in consideration of the design speed of the road, which influences various geometric design features such as minimum stopping sight distance, minimum horizontal curve radius, and maximum grade (AASHTO, 2018). The American Association of State Highway and Transportation Officials (AASHTO) recommends using above-minimum criteria where practical (AASHTO, 2018) and, ideally, the statutory speed limit should be set at or below the highway's prevailing design speed. In most countries, speed limits are set using different criteria, including mobility and environmental considerations, though safety is typically the overarching criterion. In some countries, such as Finland (Kallberg and Toivanen, 1998) and Sweden (Lynam et al., 2005), there is an effort to set speed limits such that road-user or societal costs are minimized. Higher speeds result in lower cost for travel time, but higher costs for safety, gasoline consumption, vehicle maintenance, etc. As such, the speed limit should be set close to the minimum total cost. Environmental costs can be part of such a cost analysis, and from January 2020, the top speed of 130 km/h (81 mph) on Dutch freeways was reduced to 100 km/h (62 mph) between 6 a.m. and 7 p.m. in an attempt to cut emissions (Spiegel, 2020). Similar efforts have been discussed in other countries, including Germany (The Local, 2019) where much of the Autobahn operates without a federally mandated speed limit.

Some sections have geometric features with design speeds that are lower than the statutory speed limit, with a typical example being horizontal curves with below-minimum radii. Such curves introduce the need for advisory speeds, informing drivers that the inferred design speed of these features is less than the posted speed limit. It is important to note that these speeds, as the name implies, are advisory in nature and non-compliance with these advisories is typically not enforceable. In contrast, on extended sections of highways with speeds below the statutory limit, referred to as speed zones or altered speed zones (FHWA, 2012), a lower posted speed limit can be introduced.

In addition to design speed, the operating speed of the roadway has historically been a predominant factor in establishing the posted speed limit, and still is in at least parts of the United States. Consideration of operating speed assumes that most drivers are capable of selecting appropriate speeds according to traffic, road, and weather conditions and, also, that these drivers will operate at reasonable and prudent speeds. To this end, the Manual on Uniform Traffic Control Devices (MUTCD) states that speed zones shall only be established on the basis of an engineering study, which shall include an analysis of the current speed distribution of free-flowing vehicles. The MUTCD also states that "when a speed limit within a speed zone is posted, it should be within 5 mph of the 85th percentile speed of free-flowing traffic" (FHWA, 2012). The 85th percentile speed is that speed at which 85 percent of all drivers travel at or below under ideal, free-flow traffic conditions.

The Relationship Between Speed and Safety

The 85th percentile speed has been referenced directly in the MUTCD since the 1971 edition (FHWA, 1971) while its use as a basis for speed limit determination was used as early as the 1940s (TRB, 1998). The 85th percentile speed emerged as a determinant in speed limit selection based upon one of the earliest and most frequently referenced studies in the area of speed-safety research, which compared the estimated speeds of crash-involved vehicles with field-measured speeds from control vehicles on the same general day-of-week and time-of-day (Solomon, 1964). The results, illustrated in Fig. 2, present the crash involvement rate (per 100 million

Figure 2 Crash rates by travel speed and variation from average speed (Solomon, 1964).

vehicle-miles of travel) with respect to travel speed (Fig. 2A) and with respect to variation from the average speed of traffic under similar conditions (Fig. 2B).

Collectively, these figures suggest that crash risk (i.e., possibility of being in a crash) is greatest at very low speeds and very high speeds, with vehicles traveling approximately 6 mph (10 kph) above the average speed exhibiting the lowest crash rates. However, subsequent research has shown that the crash risks at lower speeds are significantly overstated as 44% of these crashes involved low-speed maneuvers (e.g., vehicles turning into or out of traffic) and an analysis of the data excluding these maneuvers demonstrated crash risks were much less pronounced at low speeds (West and Dunn, 1971). A series of additional studies in Australia (Fildes et al., 1991), Switzerland (Finch et al., 1994), and the United Kingdom (Maycock et al., 1999; Quimby et al., 1999; Taylor et al., 2000) showed individual crash risk to consistently increase with increases in speed.

From a speed limit policy perspective, these trends suggest that drivers traveling at very high speeds are responsible for a disproportionate share of traffic crashes. This explains, in part, why setting the speed limit near the 85th percentile speed has become common practice. However, reliance on the 85th percentile speed as the primary factor in speed limit determination has come under criticism, with a National Transportation Safety Board (NTSB) report concluding that there is not strong evidence that the 85th percentile speed equates to the speed with the lowest crash involvement rate on all road types (NTSB, 2017). Furthermore, increasing speed limits to align with the 85th percentile speed may lead to higher operating speeds, resulting in a cycle of speeds escalation and reduce safety (Donnell et al., 2009).

The same NTSB report concludes that speed increases both the likelihood of being involved in a crash, as well as the severity of crash-involved occupants (NTSB, 2017). The relationship between speed and severity is generally straightforward, with increases in speeds resulting in more severe injuries by crash-involved occupants (ITF, 2018). However, the risk of crash involvement is very complex and influenced by various characteristics of both the driver and roadway environment.

A Swiss study compared changes in crash rates with respect to changes in average speeds using data from Denmark, Finland, Switzerland, and the United States (Finch et al., 1994) and showed fatal crashes to decrease by 12% when speed limits were lowered from 130 km/h (81 mph) to 120 km/h (75 mph). In aggregate, data from all four countries showed crash rates to increase consistently with speed, as illustrated in Fig. 3.

To this end, several meta-analyses have been conducted to provide insights as to the general relationship between mean speed and crash risk. A common form for this relationship is a power model, which relates the number of crashes after a speed limit change to the number of crashes before the change as a function of the ratio of mean speeds between these periods (Nilsson, 2004). The model takes the following general form:

$$\text{Crashes}_{\text{after}} = \text{Crashes}_{\text{before}} \cdot \left(\frac{\text{Speed}_{\text{after}}}{\text{Speed}_{\text{before}}} \right)^{\text{exponent}}$$

In this basic form, the exponent reflects the rate at which crashes change with respect to a relative change in speed. Data from 115 studies, which included 526 estimates of the relationship between changes in mean speed and the number of crashes or crash-involved injuries, show crash risk to consistently increase as speed increases (Elvik, 2013). Empirical results utilizing the power

Figure 3 Change in crash rate with respect to average speed (Finch et al., 1994).

model suggest that a 1% increase in average speed results in increases in the average frequencies of injury, severe injury, and fatal injury crashes of 2%, 3%, and 4%, respectively (ITF, 2018).

Subsequent research has supported this general relationship (Castillo-Manzano et al., 2019), though an exponential function has been shown to provide improved fit as compared to the power model as shown in Fig. 4. This result implies that the impacts of the speed differential are greater at high initial speeds as compared to low initial speeds, which is particularly important, as these higher speeds are generally reflective of travel on rural highways. This summary is based upon aggregate-level data from various studies, though a subsequent meta-analysis has shown a similar relationship between speed changes and crash risk when considering individual drivers (Elvik et al., 2019).

A subset of the data from Fig. 3 were used as a part of the meta-analysis that investigated the impacts of speed limit changes on both mean speed and crash risk (Musicant et al., 2016). When speed limits were increased, the mean speeds increased, but to a lesser degree than the actual increase in limits. When speed limits were reduced, the reduction in mean speeds also tended to be inelastic as compared to the change in limits. However, the average impacts on traffic crashes and injuries was shown to be nearly proportional to the change in speed limits.

History of Speed Limit Policy in the United States

The preceding discussion demonstrates that the frequency and, particularly, the severity of crashes are both impacted by changes in travel speeds. These findings are further reinforced by research that was conducted in response to three major legislative actions that have influenced speed limit policies across the United States:

1. The Emergency Highway Energy Conservation Act of 1974 mandated a National Maximum Speed Law (NMSL) of 55 mph. The primary motivation of this legislative action was to reduce fuel consumption in response to the embargo put in place by the Organization of Petroleum Exporting Countries (OPEC). However, the NMSL was extended, in part, due to a reduction in traffic fatalities that occurred during this same period. An analysis of crash data from 1952 to 1979 estimated that traffic fatalities decreased by 7466 per year as a result of the speed limit reduction (Forester et al., 1984).
2. One issue that arose with the introduction of the NMSL was that observed driving speeds did not necessarily reflect the new lower speed limits. This was particularly true on rural interstate highways where posted speed limits were significantly below the design speeds of these roadways. In 1987, the Surface Transportation and Uniform Relocation Assistance Act (STURAA) permitted states to increase speed limits from 55 to as high as 65 mph on interstate highways in areas with populations of less than 50,000. Following the enactment of the STURAA, a series of evaluation studies showed increases in traffic crashes and/or fatalities in states where the speed limit had been increased. The average increase in fatality risk during this period was estimated at 19% when controlling for other pertinent factors (Baum et al., 1991).
3. In 1995, the National Highway System Designation Act (NHSDA) completely repealed the NMSL and gave states full autonomy to establish interstate speed limits at their discretion. As a result of this legislation, many states raised interstate speed limits to 70 mph or more, with the state of Montana introducing a “reasonable and prudent” speed limit law from 1996 to 1999. The repeal of the NMSL led to a series of additional studies, which estimate an average increase of 17 percent in traffic fatalities following these increases (Farmer et al., 1999). A follow-up study concluded that the increase in speed limits accounted for approximately 12,545 additional fatalities from 1990 to 2005 (Friedman et al., 2009).

Figure 4 Comparison of power model and exponential function for injury crashes as a function of mean speed (Elvik, 2013).

Figure 5 Annual rural interstate fatality rates by maximum speed limit (Davis et al., 2015).

Collectively, the research literature shows that fatalities on rural interstates are consistently higher among those states with higher maximum statutory speed limits. However, research has also shown that the safety performance of these facilities to have improved

over time regardless of the maximum limit. Fig. 5 illustrates the differences in fatality rates with respect to the maximum statutory limit from 1999 through 2011 (Davis et al., 2015). At the aggregate level, these data show that fatality rates were markedly higher in states with 70 mph rural interstate speed limits and, particularly, in those states with speeds limits of 75 or 80 mph, as compared to states with 65-mph maximum limits. Over this 13-year period, states in each category experienced similar trends, with fatality rates remaining relatively stable through 2005, followed by a period of significant decreases, which is reflective of overall fatality trends in the United States during this same period.

Differential versus Uniform Limits for Trucks and Buses

Historically, the speed limits for trucks and buses have been a particular concern given their large size and weight, which results in restricted maneuverability, longer stopping distances, and higher impact forces in a collision. These concerns have led to the introduction of differential speed limits (DSLs), where the maximum speed limits for trucks and buses is set lower than the limit for passenger cars. In the early 1960s, the majority of states posted lower speed limits for trucks than for cars, especially on high-speed facilities. Most of the truck limits were 5–10 mph (8.0 to 16 km/h) lower than passenger car limits; however, in some states the differential was 15 mph (24 km/h). In most European countries, medium and heavy trucks are limited to 80 or 90 km/h (50 or 56 mph) on freeways whereas passenger cars typically are allowed to travel at 120 km/h (75 mph) or faster on freeways in almost all European countries (SafetyNet, 2009).

While lower speed limits for larger vehicles help to mitigate concerns with respect to high impact forces in truck- and bus-involved collisions, these differential limits potentially increase the variability in travel speeds and may increase the potential for truck-involved crashes. In light of this concern, numerous states subsequently transitioned to a uniform speed limit (USL), which establishes one maximum speed limit for all vehicles (English and Levin, 1978). On the other hand, Germany has no speed limit for passenger cars on a substantial portion of its freeways—and many drivers travel well above 130 km/h (81 mph)—whereas trucks are limited to 80 km/h (50 mph). In spite of this, German freeways have a lower overall fatality rate (0.25 per hundred million vehicle miles (HMVM) in 2017) than US freeways (0.79 for rural and 0.48 for urban segments in 2017). So, limiting the speeds of heavy vehicles may have net safety effects even if it leads to higher variation in speeds. It should also be noted that freeways in Germany often are congested, so average speeds are much lower than top speeds. And, European road safety in general is higher than that in the United States. So, the fact that Germany has no speed limit on some of its freeways should not be seen as an endorsement of that if we want safe roads. The United Kingdom, which has among the lowest top speed limits of any European country (70 mph or 110 km/h), had a fatality rate on freeways that was half of the German, one or 0.80 per billion vehicle km traveled, just below 0.13 per HMVM (Bundesanstalt für Straßenwesen, 2019).

Following enactment of the STURAA, 12 of the 40 US states that raised the maximum speed limit retained lower limits for trucks than for cars. A study by the National Highway Traffic Safety Administration (NHTSA) (1988) study in found few fatal crashes on rural interstates involving passenger cars and tractor-trailers and an effect of differential limits could not be determined. While there

Figure 6 States with differential and nondifferential freeway speed limits.

Figure 7 Annual rural interstate fatality rates by truck/bus speed limit policy (Davis et al., 2015).

has been extensive research comparing DSLs and USLs, a strong consensus has not emerged. A summary of the speed differences and crash impacts of differential speed limits for trucks on freeways was provided in *TRB Special Report 254*, which concluded, “a strong case cannot be made on empirical ground in support of or opposition to differential speed limits” (TRB, 1998). Subsequently, additional states have transitioned from differential to uniform laws and, as of October 2019, there were eight states with DSLs in place as shown in Fig. 6. On the other hand, all 28 European Union countries currently (January 2020) have DSLs.

Fig. 7 presents summary data, which compares the fatality rates between US states with uniform and differential freeway speed limits for trucks and buses from 1999 through 2011. States with differential limits exhibited slightly lower fatality rates, particularly from 2002 to 2008. However, the most recent data do not indicate a clear difference between these groups.

Effects of Speed Limits on Actual Speeds

In addition to the safety impacts of speed limits, another area of substantive debate is how speed limits influence the actual speed selection behavior of drivers. According to AASHTO (2018), driving speeds are affected by the physical characteristics of the road, weather, other vehicles, and the speed limit. Among these, road design is a principal determinant of driving speeds. Geometric factors tend to have particularly pronounced impacts on crashes. Ultimately, many factors affect speed selection beyond just road geometry and posted limit and research has generally shown that speed limit changes result in changes in the observed mean and 85th percentile speeds that are less pronounced than the actual speed limit changes (Freedman and Esterlitz, 1990).

This has been true for cases where speed limits were increased or decreased. One of the most extensive studies in this area investigated the impacts that raising or lowering posted speed limits on non-limited access highways had on driver behavior (Parker, 1997). Speeds limits were adjusted by as much as 20 mph (32.2 km/h) and, interestingly, the difference in speed after these changes was less than 1.5 mph (2.4 km/h) on average. This is one of several studies demonstrating that drivers select their speeds on non-limited access highways primarily on the basis of roadway geometry and traffic characteristics rather than the posted speed limits per se. A meta-analysis of research from the United States and various European countries showed similar results (Wilmot and Khanal, 1999).

Feedback from drivers reinforces this point. A national survey conducted in the United States in 2003 gathered information regarding driver attitudes and behaviors related to violating the speed limit and other unsafe driving behaviors (Royal, 2003). Results

showed that most drivers believe they can drive 7 to 8 mph (11.3–12.9 km/h) above the posted speed limit before being pulled over. While 51% of drivers admitted to driving 10 mph (16.1 km/h) over the posted speed limit, 68% felt that other drivers violating the speed limit were a danger to their own personal safety. Drivers reported that the most influential factors dictating their speed selection were weather, their perception of what speeds were “safe,” the posted speed limit, traffic volume levels, and the amount of personal driving experience they had on a particular road.

Two-Lane Rural Highways and Speed Limits

The discussion earlier has focused on speed limits on limited-access freeways, also called motorways. These are the types of roads with the highest speed limits, and also the highest volumes of traffic. For example, at least 27 US states allow for higher posted speed limits on freeways as compared to non-freeways while the remaining states provide the same maximum speed limit for both roadway types (Gates et al., 2015). These higher speeds are desirable since freeways are also the safest when considering crash risks per distance traveled. The reason for this is that freeways are designed to higher standards. They are divided by a median and typically include grade-separated interchanges as opposed to stop-controlled intersections. These differences virtually eliminate certain types of crashes, including head-on and angle collisions. In the United States, freeways carry 25% of all vehicle miles traveled (VMT), and 26% of rural VMT (FHWA, 2020).

However, the most recently available traffic fatality data (NHTSA, 2020) show that rural interstates experienced 1,685 fatalities whereas rural non-interstate facilities saw 13,053 fatalities. The latter group includes rural two-lane highways where safety is obviously also of great importance as such roads experience a disproportionate number of head-on collisions, as well as run-off-road crashes into roadside areas with hazardous fixed objects such as trees, utility poles, etc. Speeds, and speed limits, on such roads are obviously equally important. The majority of US states operate with 55 mph (89 km/h) or 65 mph (105 km/h) maximum speed limits on two-lane highways, though several states post limits as high as 70 or 75 mph (113 or 121 km/h) (Gates et al., 2015).

Figure 8 Rural interstate fatalities by maximum speed limit. (Sources: NHTSA Fatality Analysis Reporting System and FHWA Highway Statistics Series).

In general, the extant research literature has focused predominantly on limited access freeways. This is due, in part, to the fact that there is significant variability in the design characteristics of two-lane highways, where speeds can range from 25 to 75 mph (40–121 km/h). Continuing on this point, one concern that is unique to rural two-lane highways is the presence of speed reduction zones when such highways pass through incorporated cities or towns. Guidance is provided for local agencies in National Cooperative Highway Research Program (NCHRP) Report 737 for the implementation of such speed transition zones (Torbic et al., 2012). Several potential factors have been shown to affect drivers' selection of operating speeds as they enter speed reduction zones (Cruzado and Donnell, 2009, 2010). The magnitude of the speed reduction and other characteristics, such as lane width, paved shoulder width, and lateral clearance tend to reduce operating speeds entering a speed reduction zone.

Overall, the safety literature generally suggests that increasing speed limits on non-freeways will result in an increase in the overall crash rate and will also result in a higher proportion of more severe crashes due to the increase in the energy dissipated during crashes due to vehicles traveling at higher speeds. An NCHRP study estimated that increasing the speed limit from 55 to 65 mph (89–105 km/h) would increase the total crash rate by 3.3%, and the probability of a fatality (assuming a crash had occurred) would increase by 24% (Kockelman, 2006).

It should be noted that Sweden, which is one of the countries with the lowest fatality rates in the world, lowered the speed limits on most of its two-lane roads and other roads where head-on collisions are possible from 90 km/h (56 mph) or 100 km/h (62 mph) to 80 km/h (50 mph) in 2019 (ITF, 2019). Prior to the year 2000, many of those roads had a speed limit of 110 km/h (68 mph). However, some of the two-lane roads have had continuous centerline barriers installed, and the speed limit on these have been kept at, or increased to, 100 km/h (62 mph). As of 2019, there are around 1800 speed-enforcement cameras on rural roads in Sweden to enforce these speed limits. The reduction of speed limits and speeds are often credited with Sweden having seen an 83% reduction in the number of traffic fatalities since they peaked in 1966 at the same time as its population has increased by 32%. Sweden in 2019 had 2.16 fatalities per hundred thousand inhabitants whereas the United States has a population rate over 5 times that (WHO, 2020). The difference can be partly explained by higher travel speeds in the United States but also because of more automobile travel in general in the United States. But even if we account for the latter, the fatality rate per HMVMT is around 0.42 in Sweden and well over 1 in the United States.

Current Practices in Setting Speed Limits

As noted previously, 18 states have increased their maximum statutory speed limits to 75 mph or above. The preliminary evidence, as demonstrated in Fig. 8, shows that states with higher limits tend to experience consistently more fatal crashes than states with lower limits. Furthermore, one important contrast as compared to prior changes, such as those following the three speed limit law changes discussed previously, is that the more recent increases have generally been done selectively based upon traffic engineering, speed, and safety studies conducted by the state departments of transportation.

This is an important distinction as not all segments of a particular roadway class are likely to be acceptable candidates for speed limit increases. In particular, segments with extensive horizontal or vertical curvature, sight distance limitations, or other features that may not comply with current design standards (e.g., design exceptions) may not be suitable for speed limit increases. Similarly, locations at which prevailing speeds are generally aligned with the existing speed limit or locations where there is a history of crashes may not be suitable candidates for increases.

Increasing speed limits also introduces important economic considerations, including the costs required for geometric modifications (e.g., vertical or horizontal realignment) to satisfy minimum design criteria at higher design speeds. Consequently, increases to the higher ranges of speed limits should be considered only if the critical geometric elements can maintain design speed compliance without major modification. However, even for roadways on which design speed compliance is maintained, careful, site-specific consideration must be given to the potential safety impacts, particularly with respect to fatal and injury crashes, which may result after the speed limit is increased.

A 2018 survey conducted by the National Committee on Uniform Traffic Control Devices (NCUTCD) Task Force shows that those professionals who perform posted speed limit studies rarely use only the 85th percentile speed and, instead, consider the context of the roadway where the speed limit change is being considered (Fitzpatrick et al., 2019). This includes the factors explicitly noted in the MUTCD that may be considered when establishing or reevaluating speed limits, which include road characteristics, roadside development, and reported crash experiences.

Moving forward, the establishment of maximum speed limits in rural areas will likely continue to be an area of substantive interest to researchers, legislatures, and the traveling public. While additional research is warranted to fully understand the nature of these relationships, agencies should exercise caution whenever speed limit increases are under consideration. The impacts of emerging concerns, such as distracted driving and the integration of connective and autonomous vehicles, are among the issues that prompt the need for such scrutiny.

Introduction

Streets and roads form the foundation of travel and interaction in urban areas, as well as constituting most of the public space in cities. The concept of what streets are for and how they are used has changed over time, and continues to change, generating both opportunity and conflict that must be managed through an ever-evolving framework that includes political leadership, law, policy, regulation, design, monitoring and evaluation, and community participation. The interplay between all of these factors is relevant for setting safe speed limits.

The current situation in many urban areas around the world is streets that favor high speeds and a prioritization of space for moving and parked vehicles over other mobility and community needs. Allowing high speeds has resulted in urban areas that generate a high proportion of crashes that cause death and injury to people walking, biking, or using other human scale means of transport, act as a deterrent to these mobility modes for people who can afford other options, and degrade the urban environment with noise and air pollution. As the body of evidence demonstrating the direct link between vehicle speeds and crashes, deaths and serious injuries, the understanding of how and why speed limits are set in urban areas has responded accordingly, and efforts are now underway in many cities around the world to proactively determine and achieve safe speed limits and safe operating speeds. As well as the aforementioned safety benefits, but such speed limits also generate many co-benefits such as improved quality of life, accessibility, economic development, and more efficient fuel consumption, generating a positive cycle for urban areas.

Speeds are especially dangerous for vulnerable road users, pedestrians, cyclists and motorcyclists, as they do not have a protection of metal around their bodies as car drivers do. In case of a road crash, they receive the force of the impact directly into their bodies, and the higher the speed the higher the severity of the injuries. Lowering speeds results in more people walking or cycling as the risk of being involved in a road crash decreases, and these travel options feel safer and more comfortable. Low speeds are key to promoting active transport.

History/Evolution of Speed Limits in Cities

Historically, streets were used for walking or traveling at sedate speed by horse. In 1652, the American colony of New Amsterdam passed a law stating that "No wagons, carts, or sleighs shall be run, rode, or driven at a gallop." The punishment for breaking the law was "two pounds Flemish," the equivalent of US \$50 today. In the 1800s, bicycles and trams (streetcars) were added to many urban streets, but traffic still moved at human pace. The first numeric speed limit was the 10 mph (16 km/h) limit introduced in the United Kingdom in 1861. But that turned out to be too high for public comfort, so, by resident demand, it was reduced to 2 mph (3 km/h) in towns and 4 mph (6 km/h) in rural areas by the 1865 "Red Flag Act." In the United States, the first numerical speed limit for motor vehicles was set in 1901 in Connecticut with a maximum legal speed of 12 mph (19 km/h) in cities and 15 mph (24 km/h) on rural roads. In 1903, in the United Kingdom, the national speed limit was raised to 20 mph (30 km/h). In other words, streets were still low-speed environments where many users mingled and negotiated shared use of space on foot, bicycle, carriage, or public transport, such as trams. When cars became somewhat more common, this dynamic stayed much the same. But as the speed capacity and volume of cars grew, and the first fatalities caused by cars occurred, the discussion began to shift. Initially the expectation was on car companies and city regulators to limit the speed of cars and preserve the safe interaction and intermingling of many different types of

transport on the street. But influence from car companies and driver associations gradually shifted the expectation of what streets were for and what appropriate speed limits were, until other types of uses were pushed off streets and confined on sidewalks, and cars moving at much higher speeds became the default use of most streets. The type of road and urban areas that have been designed or evolved since private car use became widely accessible have further compounded the role of streets as thoroughfares for fast moving motor vehicle traffic.

Unfortunately, this shift towards a focus on streets as serving the sole purpose of moving (or parking) cars has resulted in a prevalence of urban environments that are hostile to people who are not in vehicles. The statistics on this are clear. Most victims of traffic fatalities and serious injuries in urban areas are so called “vulnerable users,” that is, people who are walking, bicycling, or otherwise traveling outside of a vehicle. For example, in New York City in 2018, 114 pedestrians, 10 bicyclists, and 39 motorcyclists were killed in comparison to a combined total of 37 car and truck occupants. That adds up to 200 deaths, the lowest in over a century, which certainly is an improvement over the 1360 deaths seen back in 1929, or the 701 traffic deaths as recently as 1990. However, more pedestrians died in New York in 2018 than in the year before. While safety for vehicle occupants, particularly in wealthy countries, has steadily improved, thanks to technological and legal advances regarding the use of seatbelts, airbags, and other safety devices to protect car occupants, design technology and legal requirements to protect people using the streets outside of cars have not advanced at the same pace or had the same impacts. As a result, in many places, even if traffic deaths and fatalities are declining overall, they are increasing among the most vulnerable groups. Furthermore, these hostile environments to people who are not using private vehicles have broader impacts because they affect people’s decision making about how to travel, generating significant financial, environmental and physical effects, and creating a negative feedback loop of increased car use and risk. For example, in wealthy countries, the proportion of children biking or walking to school is in dramatic decline, while childhood obesity is increasing. Meanwhile in many lower income countries women have been recorded as opting for substantially longer commutes than men in order to reduce their exposure to risk. This has a variety of negative carry-on effects on their health, access to jobs and services, and leisure time.

One traditional approach to setting or adjusting speed limits was to measure traffic operating speeds and then set the speed limit at **the 85th percentile**, that is to say, the speed that 85% of motor vehicles were traveling at or under. This method was first used in Europe. While this practice has waned there now, it is still often mentioned as a valid method in the United States and many other countries that follow the US transport planning and engineering guidance. However, this method should no longer be recommended for setting safe urban speed limits. This is because it is a reactive approach that allows the speed limits to be set based on driver perceptions and comfort with a certain speed. This is typically derived from the operating speed, which is heavily influenced by the design of the street. Unless the street has been proactively designed to generate a desired target speed, this is not likely to be the actual safe speed, both because the perception and reality of safety and comfort are very different between a vehicle occupant and a person walking, biking, or using another personal mobility device, and also because humans do not have a well-developed sense of speed and the risks associated with it, compared, for example, to our perception of the risks associated with height. Furthermore, many streets are designed in a way that is inappropriate for their current use or range of users (for example, traditionally many urban areas in developing countries, lacking their own street design guidance, have applied the US highway design guidance to streets in urban areas). In these cases, it is the design of the street that should be adapted to the needs of the location, rather than the speed that should be adapted to the design.

In other places, speed limits are set according to the type of road, in terms of its predominant purpose as a thoroughfare or local point of access. This is often referred to as “function” or “classification.” In this case, roads designated as arterials usually have higher default speed limits than roads designated as intermediate or local roads. However, most roads, especially long ones in larger cities, can vary from block to block in terms of adjacent land use and thus types of activity and road users present, or adjacent land uses can change over time, such as residences constructed on previously undeveloped or industrial land. Therefore, the default speed limit should not be rigid, but adjusted for particular needs. For example, a commercial center on an arterial road, that concentrates more pedestrians than other parts of the road. If the road classification does not take into account other variables as the context, road conditions, or quality of infrastructure for vulnerable road users in this way, then the speed limit may still not be appropriate, and the classification may also need to be reviewed. For more information, see the subsequent section, “Considering road function when establishing speed limits.”

The Safe System Approach and Speed Limits

The Safe System approach to road safety reframes the way streets and mobility systems in cities operate to place safety at the forefront, particularly the safety of the most sustainable, yet vulnerable, forms of transport—walking and cycling. This is in contrast to the status quo that has emerged in most regions of the world over the past 100 years that has placed private cars at the center of the mobility and safety planning system to the detriment of safety and accessibility of other types of transport. The Safe System approach, also referred to as Vision Zero in this Encyclopedia, has as its foundation the principle that **no serious injury or loss of life** is an acceptable trade-off for “efficiency” or “modernity.” People will always commit errors, and the mobility system should be designed to mitigate the possibility and severity of these, so that no one has to pay with their life or permanent disability (Welle et al., 2018).

Establishing appropriate speed limits, target speeds, and operating speeds is therefore a fundamental element of a safe mobility system, as speed is the key determinant of whether a crash happens at all, and if so, how severe it is. This is for several reasons. At

Higher vehicle speeds require longer stopping distances

Figure 1 Combined reaction and braking distances required at various speeds. Note: The above distances are minimum distances. The total stopping distance also depends on the road surface, weather conditions, and age/condition of the vehicle. Source: Graphic prepared by World Resources Institute (WRI) with data and calculations supplied by Per Garder.

higher speeds, drivers have reduced peripheral vision. Driving at very high speeds can result in a combination of tunnel vision and decreased depth perception for the driver. At lower speeds, drivers have a wider field of vision and are more able to notice other road-users and any unexpected obstacles or events that they need to react to. Driving at lower speeds also enables drivers to stop within a shorter distance (Job and Sakashita, 2016). This is because the stopping distance of a vehicle is a combination of the distance traveled during the driver's reaction time and the distance it takes for the car to stop after the brakes are applied. At higher speeds, a car will travel further during this reaction time and due to momentum, the braking distance is also greater, and proportional to the speed squared. Another way to put this is that the impact of increased speeds is not linear but increases exponentially. The same rule applies to risk of death or serious injury.

For example, with good tires and dry pavement, and a typical reaction time of 1.0 s, a driver could stop in 11.8 m if the car is driven at 30 km/h and they brake as hard as possible (8.3 m in reaction distance and 3.5 m to brake). If the car instead is driven at 50 km/h, it would need 23.7 m to stop (13.9 m in reaction distance and 9.8 m to brake). So, if a driver experienced an unexpected event with a pedestrian appearing 12 m in front of them, and they were driving at 30 km/h, the driver would be able to stop in time to avoid hitting them, but if they were traveling at 50 km/h, they would not even have started to brake and would hit that pedestrian at 50 km/h. This would potentially cause serious injury or death. Even if they were traveling at a speed of 40 km/h, they would need 17.4 m to stop totally, so they would hit the pedestrian without managing to slow down by more than a couple of km/h (6.3 m reaction distance and 11.1 m braking distance). On the other hand, if the vehicle were traveling at 20 km/h, they would be able to stop in just over 7 m (5.5 m reaction distance and 1.6 m braking distance) giving them a margin of almost 5 m (Fig. 1) (Garber and Hoel, 2015). It is important to note that the distances given here are for a best-case scenario with good vehicle and road conditions. If their tires were worn or the pavement was wet, they would use up much of that 5-m margin for coming to a full stop. Speed thus clearly affects the possibility of a pedestrian's survival in the case of an incident on the road. Impact speed is particularly pertinent to consider when there are people walking and biking, whose bodies much more are exposed to the impacts of a crash than occupants of cars, trucks, and buses who are protected by the body of the vehicle.

Furthermore, a safe speed limit, which generates a safe operating speed thanks to infrastructure, regulation and police control, will reduce variation between the speeds of different vehicles on the street, and the related issue of risky mid-block acceleration.

Another key principle of the Safe System approach is that road safety should be tackled in a **proactive** manner, rather than a reactive one. In the context of speed limits, this means that safe limits should be established based on an analysis of multiple factors at hand, such as the types and volumes of different road users, the function of the road, adjacent land uses, any available data on near-misses or adapted travel patterns caused by perceived risk and discomfort, and the quality and adequacy of the infrastructure present, particularly at intersections, rather than as a reactive response based on the current operating speeds of vehicles, the original intent of the street (which may change over time), or to crashes only once they do happen.

Speed Limits and Operating Speeds

The **speed limit** is the legal speed permitted on a street under local, state, or national traffic laws or regulations. The purpose of a speed limit is to align the vehicle speeds on a street or road with the function, dynamics, context, and road users present, to create a predictable environment and avoid dangerous speeds. However, setting a speed limit is just the first step in achieving compliance with this limit. Ensuring that drivers follow speed limits requires a variety of enforcement, regulation and design, and awareness raising measures implemented in combination. One mechanism for this that is well proven in evidence is roads that are designed to be “self-enforcing,” that is, roads that have physical design features such that it is difficult or impossible for a vehicle to exceed the designated speed limit. Driver compliance with the speed limit can also be monitored and enforced by a specific authority, such as a police or traffic agent that is attributed with the power to issue a warning or fine directly to a driver, or via automated technology such as speed cameras. Speed limiting vehicle technology is also increasingly available and presents a significant opportunity to complement or reduce the need for enforcement. Street designs that relate directly to the speed limit and **desired operating speed**, also known as the **target speed**, should be complemented by other approaches such as integrating driver awareness and understanding of typical speed limits into driver education and licensing processes, and posting the speed limit in highly visible locations.

The actual combination of mechanisms applied to achieve compliance with the speed limit in a given location should be determined based on local conditions including: function and type of road, land-use, dynamics, road users present, street construction materials, design guidelines and policies, the culture of legality, law enforcement funding and priorities, access and cost of automated technology, the influence of national and state level laws on local enforcement attributions, and maintenance.

It is important to note that the speed limit alone does not actually determine the **operating speeds** in a street, neighborhood, or urban area. The operating speed is the actual speed that vehicles travel in a given street and has a direct impact on safety. Actual operating speeds can be significantly higher, or lower than the speed limit, or have major temporal variations. This is due to a variety of factors; mainly to what extent the mechanisms for compliance listed above are implemented. Limits may not be posted or enforced at all; speed regulation may include a degree of “tolerance” before enforcement is triggered; the physical design of the road may be out of line with the speed limit and allow drivers to feel comfortable moving at higher speeds (or the reverse). In addition, in many urban areas, traffic congestion, primarily caused by vehicle volume, and traffic conflicts, may mean that during peak times, vehicles move much more slowly than the posted limit.

For the same reasons, it is important that in addition to setting a safe speed limit, authorities ensure that the factors are in place to also generate a **safe operating speed**, that is, below or at the legal speed limit. This known as setting a **target speed**. Research has found that a regulation change such as lowering the posted speed limit typically only yields a reduction of a few kilometers/hour in average speeds if the change is made in isolation, indicating that proactive mechanisms for enforcement, either by enforcing agents or automated systems, as well as context-appropriate street design are necessary to achieve genuinely safe operating speeds that reflect the speed limit and desired target speed.

Traditionally, wide lanes, number of lanes and other street design factors such as long blocks, as well as a typical “tolerance” of 10 km/h or 10 mph before enforcement of speeding fines has meant that the de-facto speed limit is often substantially higher than the actual limit. The evidence shows that this can be the difference between life and death in a crash situation, so for a safe speed limit to truly be safe, it must be accompanied by a similarly safe operating speed. If there is concern about the limitations of enforcing speed limits at low speeds, or with no “tolerance” for excesses, then street design techniques may be applied to create a street environment that is “self-enforcing” by making it physically difficult or impossible for a driver to negotiate the street at a speed higher than the speed limit.

Safe Speed Limits for Urban Areas

Under the Safe System approach, a “safe” **speed limit** is considered one where most crashes can be avoided, and if one did occur, then those involved would have a 90% or more chance of survival and avoid permanent injury. This means that speed limits should be responsive to the specific types of users on that road. For example, an urban street with a commercial land use, and a high presence of people walking, biking, or using other human scale means of transport such as scooters, strollers, or wheel chairs, or where bicyclists share the road with drivers without any physical segregation of infrastructure—should have a speed limit of 30 km/h or less. This is because research has found that above approximately 30 km/h, the risk of a fatality in a crash with an unprotected human increases exponentially.

Data for pedestrians struck by a car or light truck in the United States from 2007 to 2009, shows that the average risk of severe injuries for a pedestrian struck by a vehicle reaches 10% at an impact speed of 26 km/h (16 mph), 25% at 37 km/h (23 mph), 50% at 50 km/h (31 mph), 75% at 63 km/h (39 mph), and 90% at 74 km/h (46 mph). The average risk of death for a pedestrian reaches 10% at an impact speed of 37 km/h (23 mph), 25% at 51 km/h (32 mph), 50% at 51 km/h (42 mph), 75% at 80 km/h (50 mph), and 90% at 74 km/h (58 mph) (Fig. 2). However, averages can be misleading, because risks vary significantly by both victim and contextual factors, such as age, gender, quality of emergency response and hospital care, and local vehicle fleet (Tefft, 2011).

It is important to note that most of this type of research has been undertaken in wealthy European countries and the United States where emergency response and hospital care is rapid and well-coordinated, which likely contributes to higher likely survival rates at these speeds than in countries with poorer access to medical care, such low- and middle-income countries where the majority of traffic fatalities are concentrated.

Figure 2 Average risk of pedestrian death or serious injury at various vehicle speeds from US data 2007–2009. Note: The above values are averages taken from one study based on the US data from 2007–09. The likelihood of survival will vary in specific cases depending on characteristics of the victim and vehicle and location involved, such as, age, gender, stature, vehicle type, speed, and quality of emergency response services. Source: Graphic prepared by World Resources Institute (WRI) with data from Tefft, 2011.

As an example of the impact of the local vehicle fleet on risk, the situation for pedestrian safety in the United States has declined over the last decade, since the above numbers were calculated, and one contributing factor is that the proportion of trucks and SUVs in the vehicle fleet has continually increased. Due to the height of the hood of such vehicles, even adults are knocked down in front of the vehicle if hit. In contrast, car design standards in Europe include design requirements to mitigate pedestrian injuries, a feature not required for cars in other regions that typically only require designs to protect the vehicle occupants.

With regard to age and gender and risk, the average risk of severe injury or death for a 70-year-old pedestrian struck by a car traveling at 40 km/h (25 mph) is similar to the risk for a 30-year-old pedestrian struck at 55 km/h (35 mph). Additionally, based on the history of both crash test dummy design based on average male measurements, and analysis of crash victims, which are predominantly male, it is likely that this research is skewed toward impact on the male body, so for women, the safe speed limit may be even lower. This is certainly the case when it comes to children, who are more vulnerable not just because their fragile bodies and less developed bones are less able to withstand a crash and their lower center of gravity and shorter stature means that they are more likely be knocked down in front of cars rather than land on the hood, and to receive upper body and head injuries, but also because they are more difficult for drivers to see, and do not yet have fully developed speed perception or impulse control. For this reason, appropriate speed limits around schools should be set even lower than other urban streets; ideally 20 km/h or lower. A lower limit (10–20 km/h) may also be appropriate in the case of street design types or functions where street space is shared between people driving vehicles, walking, playing, and bicycling.

Many countries have also long set a **default maximum speed limit of 50 km/h** in urban areas, however research has found that this is too high to be a safe general speed limit in urban roads with a high prevalence of vulnerable users. This speed limit is best reserved for high traffic volume key arterials within cities, applied in conjunction with segregated infrastructure for people biking and walking and accessing public transport, and controlled intersections for safe crossing, so that the risks presented by higher speeds are counteracted by reduced exposure to risk.

In summary, the speed limit should be defined by both taking into account the function of the road and the context. Elements to consider include: the interaction or integration of vehicle traffic and vulnerable road users, the type of vehicles using the road and type of segregation between types of vehicle (e.g., the presence or absence of protected bicycle lanes), the volume and flow of traffic, the free-flowing traffic speed, the nature and intensity of surrounding land uses and infrastructure (e.g., the variety of activities/services, vehicle entryways, obstacles affecting visibility, etc.), the crash history of a location, and the design of intersections (Figs. 3 and 4) (Alcaldía Mayor de et al., 2019).

Considering Road Function When Establishing Speed Limits

One helpful mechanism to facilitate setting safe speed limits in urban areas is to establish a process of categorizing roads in terms of their function and context. Maximum speed limits can then be established for each category, with the option for local authorities to

lower the limit further depending on specific contextual details. If authorities are proactive about reviewing the default limits and adapting them to variations in the road features as necessary, a road function classification approach can facilitate the process of assigning appropriate speed limits and lowers the risk of inappropriate uses for roads. Because cities are dynamic, meaning that adjacent land uses and thus a road's purpose may change over time (e.g., urban expansion may result in a road that previous served a connecting purpose having housing built adjacent to it, adding an access purpose) road classifications should also follow a schedule of regular review and updating, in order to ensure that the classification and appropriate speed limit is appropriate to the function, or conversely, any issues with the road being used inappropriately (for example, commuters "rat running" through residential areas) are identified and addressed.

Road functions in urban areas can typically be divided into "through" functions and "access" functions. Through roads typically have a connector function, and are used to transport goods or people longer distances, a higher maximum speed limit is usually allocated to reflect this role. For example, in the Netherlands, a world leader in the Safe System approach, the maximum limit on such a road is 50 km/h. However, if the context of such a road on certain blocks is commercial, which attracts more pedestrians and generates crossing needs at different points of the road, then the speed limit in those areas should reflect that and be lowered to

40 km/h or less. The same applies for roads with an access function. These are locations where there is a concentration of residential, commercial, and/or institutional services. They should have maximum limits of 30–40 km/h. Access roads may be further broken down, either by formal classification or through other mechanisms such as design guidelines, into standard commercial or residential streets, shared streets, bicycle priority streets or play streets. Maximum or recommended speed limits may be set accordingly and be as low as 10–20 km/h in the case of streets with various types of shared status.

Benefits of Appropriate Speed Limits and Operating Speeds

Because speed is a contributing factor in the majority of crashes, setting safe speed limits and operating speeds is the fastest and most cost-effective way to reduce traffic fatalities and serious injuries, for all types of road users, but particularly people outside of cars. Moreover, the benefits of setting safe speed limits extend much more widely than this. Safe speed limits reduce both real and perceived risk for people biking and walking or using other human scale modes. The increased comfort generated reduces barriers to these active options, increasing accessibility, physical activity, and even play opportunities for children. In turn, this can generate a positive feedback loop whereby vehicle use is reduced, further reducing exposure to risk for people on the road, as well as reducing air and noise pollution, and advancing a positive feedback cycle of reduced private car use and increased use of more sustainable modes.

Reduced traffic fatalities and injuries and air pollution, and increased physical activity also have a beneficial economic impact as they reduce health costs. Furthermore, for cities battling major traffic issues, there is also emerging evidence that lowering speed limits reduces the conflicts and bottlenecks at intersection that contribute greatly to congestion. More consistent speeds and a reduction in acceleration and deceleration can both ease traffic flows and also reduce the emissions generated by cars.

Public Perceptions and the Politics of Speed Limits

The evidence of the safety benefits of taking a Safe System approach to road safety, and adjusting speed limits accordingly, is now well established. However, most countries are yet to build this knowledge into their default laws, regulations or planning policies, so there are few places where urban areas predominantly have a 30 km/h limit, and even fewer where it is the default.

This means that most places still require a review and implementation process to achieve safe speed limits in their urban areas. And, like most decisions involving public space, speed limits and use of streets are contentious and thus highly political matters, especially in urban and suburban areas that often face competing needs or demands between people commuting through them and living within them. For this reason, the local political economy must also be taken into account as it relates to setting, implementing and enforcing speed limits. Political leadership to prioritize road safety can play a major role in this process.

A common preoccupation when revising speed limits is the link between speed limits and travel times. The speed limit is frequently, but incorrectly seen as the key contributing factor to congestion in urban areas. Many people fear that lowering the speed limit in urban areas will increase journey times. However, average road speeds in cities are typically more determined by the volume of vehicles and the frequency of intersections than the speed limits. In many places, even if the speed limit of a road is 50 km/h, in a typical daytime or peak time speeds are in fact well below 30 km/h already, due to these factors. For the same reasons, if journey times are increased by the change in speed limit, it is typically by seconds rather than minutes. Conversely, emerging evidence from cities is demonstrating that lower speed limits can in fact ease congestion, by reducing traffic conflicts and bottlenecks at intersections.

After vehicle volume, distance from destination is the greatest determinant of travel time, not the speed limit. Due to a variety of factors such as the scale of urban areas, and vehicle-oriented planning or evolution into sprawl, people in all types of cities live at an increasing distance from their daily destinations, and as such are even more sensitive to anything that they perceive will increase their journey time. Applying a Safe System approach to road safety and mobility across the board can begin to address the preoccupation with journey times and congestion, because it also promotes more efficient land use arrangements that mix uses and encourage compact development, so that people live nearer to their frequent destinations. This way, safety can be improved by reduced exposure to vehicle travel or vehicles, alongside reduced speed limits.

One argument sometimes made against lowering speeds is that they can lead to higher fuel consumption. While it is true that traditional cars are the most fuel efficient at speeds of around 50 km/h (30 mph), constant low speeds of around 30 km/h (20 mph) are much more fuel efficient than the current typical urban situation of frequent acceleration and deceleration to stop at traffic signals or congested areas in order to reach 50 km/h between points. Furthermore, modern fleets are now transitioning towards hybrid and electric cars that typically get their best fuel consumption at speeds of around 30 km/h.

Cities that have successfully adapted their speed limits to safe levels for their current uses in recent years have avoided, reduced or addressed public backlash through a variety of means, including integrating speed limit changes with major physical and design upgrades of streets and public spaces, beginning with pilot projects such as “low speed zones” before scaling up the number of zones and extent of limits once the benefits are generated, developing integrated public outreach and enforcement campaigns so that drivers are more aware of the risks of speed and are exposed to verbal warnings from police for a “grace” period before new limits are enforced with fines, and conducting public consultation processes or community proposals on lowering speed limits.

Conclusion

As the concept of the Safe System for mobility is becoming more widely adopted, the concept of what safe speeds are in cities and who they should benefit has changed. There is now an increasing focus on protecting vulnerable users who typically make up most travel in cities and form the economic and social foundation of urban areas. This shift is generating measurable benefits in the places it is applied, both directly in terms of lives saved and injuries avoided, and indirectly in terms of other benefits such as increased physical activity, increased local economic activity, and improved quality of life.

As previously mentioned, establishing a safe speed limit in law at the national, state, or city level is the first step toward achieving safe speeds in urban areas, but it is not a sufficient measure on its own. Once a safe speed has been identified through a process of street classification and contextual analysis, and passed into law, regulation or policy, typically facilitated by a process of public outreach and awareness raising about the positive impacts of such a change, additional measures, specifically urban design and enforcement via police/automation or even vehicle features are necessary to ensure that driver behavior actually changes. Finally, while the changes necessary at policy, regulation, and street level are technical, they require a level of political leadership and commitment in order to be developed, introduced, and maintained, as well as to receive an adequate budget.

Introduction

The relation between speed and traffic safety is well established. Speed has been identified as a critical risk factor in road traffic injuries, influencing both the risk of a road crash and the severity of injuries. This knowledge influences speed limits for various functional classes of streets. As the accessibility of streets increases from freeways to local roads, possibilities for collisions also increase. Transportation agencies use lower speed limits to reduce the risk of severe injuries. Sometimes, setting speed limits alone would not help reducing vehicle speeds. In such cases, some interventions are required to reduce speeds. These could be engineering-based, or behavioral-based. The latter include enforcement and education. Combined, all these interventions are commonly known as speed-reducing measures.

This paper discusses the design, details of deployment, and effectiveness of some of the commonly used speed-reducing measures. This paper primarily references US-based design standards and documents.

Speed and Safety

Various studies have established that increasing the average speed by just 1.6 km/h (1 mph) typically increases the risk of crashes that result in injuries by about 4%. The same increase in speed adds 5% to the risk of fatal crashes. This happens because speed contributes to the severity of impact. For car occupants in a crash with an impact speed of 80 km/h (50 mph), the likelihood of death is 20 times what it would have been at an impact speed of 30 km/h (20 mph). The relationship between speed and injury severity is particularly critical for vulnerable road users, such as pedestrians and cyclists. For example, studies have shown that

pedestrians have a 90% chance of surviving when struck by a car traveling at 30 km/h (20 mph) or below, but that chance decreases to less than 50% at 50 km/h (30 mph). Pedestrians have almost no chance of surviving an impact at 80 km/h (50 mph).

Speed limits should be set such that the risk of fatalities from crashes is low, also see Article 10188, Speed Limits on Urban Streets; 10189, Speed Limits on Rural Highways. Typically, the risk of a fatality for the most critical crashes on that road category is set below 20%. For example, residential streets in the United States typically have speed limits of 40 km/h (25 mph). In Europe, urban street speed limits in the early 1950s were often 60 km/h (37 mph). Then they were reduced to 50 km/h (30 mph) and are now in many countries 40 km/h (25 mph) or 30 km/h (19 mph). In some cities, such as Berlin, many residential streets since 2017 have 10 km/h (6 mph) limits. In the United States, streets within school zones typically have a 25 km/h (15 mph) speed limit during times when children walk to and from them. The lower speeds intend to reduce the risk of pedestrian injuries. Similarly, most undivided urban collectors and arterials have speed limits of 50 km/h (30 mph) and sometimes 55 km/h (35 mph). Even 60 km/h (40 mph) and 70 km/h (45 mph) are used where there are no crosswalks and no pedestrians adjacent to the street. In Sweden, many rural undivided two-lane arterials used to have the speed limit 90 km/h (56 mph) but now many of those roads have been equipped with center cable barriers, and the speed limit increased to 100 km/h (62 mph) or, if they have not had barriers installed, the speed limit has been reduced to 80 km/h (50 mph) in order to reduce risks associated with head-on collisions. In other countries, 90 km/h (55 mph) speed limits are still allowed on undivided highways, and in some US states, even higher speeds are allowed.

However, speed limits alone will not always result in vehicle following posted speeds. Road design provides important cues to drivers about what constitutes a “safe” speed. And most drivers prioritize mobility and assume they will be safe at any speed, and reduce their speed more frequently to avoid tickets than to stay safe. The speed chosen by drivers is influenced by the road environment, including the road design and roadside infrastructure, and it is known as the perceived speed limit. If the posted speed limit and perceived speed limit do not match, drivers tend to deviate from the posted speed limit unless there is strict enforcement.

Driving at high speeds that are unsuitable for the prevailing road and traffic conditions has been responsible for many of the world’s vehicular injuries and fatalities. According to the World Health Organization (WHO, 2018), in some low-income and middle-income countries, speed is considered the primary contributing factor in about half of all road crashes. In high-income countries, in spite of availability to the resources to design safer roads and enforce traffic laws, speed still contributes to about 30% of deaths on the road according to some estimates. In the United States, for example, speeding has been at least partially responsible for about one-third of all vehicular fatalities over the last two decades. In Sweden, the authorities estimate that one-third of all fatalities would have been avoided in 2018 if no drivers had exceeded the existing speed limits, and more lives would have been saved if speed limits were reduced and enforced.

This goes to show that controlling speed can prevent crashes from happening and can reduce their severity when they do. However, many countries have introduced speed limits only to see them have a short-lived effect. Unless accompanied by sustained interventions, speed limits by themselves are often unable to curb speeding.

There are a few ways to reduce vehicle speeds, categorized mainly as engineering-based interventions and behavioral-based interventions. There are several resources available that discuss design, deployment strategies, and effectiveness of various speed-reducing measures. This paper refers to various resources by different agencies including the US Department of Transportation (USDOT, 2014, 2017, 2019), National Cooperative Highway Research Program (NCHRP, 2006, 2008, 2011, 2018), National Association of City Transportation Officials (NACTO, 2013), and the Institute of Transportation Engineers (ITE, 1999a, 1999b). The cost estimates mentioned for each of the speed-reducing measures (where available) are in 2017 US dollars.

Engineering-Based Measures

This category of speed-reducing measures introduces design changes to the roadway so as to enforce the desired speeds on it. One of the most popular engineering-based tools to curtail speeding is to implement traffic calming measures. Traffic calming measures are used either to reduce speeds or to reduce traffic volume. In this paper, only the measures used for reducing speeds are relevant. However, reducing the widths of streets from having two lanes in a direction to having only one lane is a fairly efficient speed-reducing measure in itself. As long as we have reasonably high volumes and a sizable proportion of drivers being law abiding, these drivers will reduce everybody’s speed to the limit. However, that strategy does not work when we have low traffic volumes or very few law-abiding drivers. Then other measures are needed, and such traffic calming measures primarily come in the form of two broadly defined types based on the design concept used to attain the desired speeds: (1) ones with vertical deflections, and (2) devices with horizontal deflections or narrowing. Due to their effectiveness and the relatively low cost of implementation and maintenance, traffic-calming measures are popular among road administrators and among residents living near them but they are often not very popular among commuters driving through areas with them. In addition to traffic calming, other engineering-based measures include active speed reduction techniques, such as speed governors (see Article 10517: Speed Governors and Limiters) and smart measures which are activated only when required.

Traffic Calming Measures With Vertical Deflections

Traffic calming devices with vertical deflections are the most common measures. Raising a small portion of a road surface creates discomfort for drivers traveling at high speeds. These devices reduce the speeds by inducing haptic vertical movement to the vehicles

passing over them and discomfort at speeds higher than the design speeds. The level of discomfort and optimum driving speeds depend primarily on geometry and type of vehicle traversing them. Examples of these measures include speed humps, speed bumps, speed cushions, speed tables, raised crosswalks, and raised intersections. Some of the commonly used ones are discussed as follows.

Speed Humps

A speed hump is a raised portion of the roadway surface extending transversely across the roadway. A common speed hump is Watts' hump, developed in England in 1973. It has a parabolic shape and a height of 10 cm (4 inches) and a length along the traveled way of 3.6 m (12 feet). The length of the hump is chosen so that a typical automobile has its front wheels move down at the same time as its rear wheels move up, increasing the feeling of vertical acceleration. Variations of this hump with slightly different dimensions, and only 75 mm height (3 inches), are sometimes used. In some cases, speed humps may raise the roadway surface to the height of the adjacent curb for a short distance. Humps can either extend the full width of the road, curb-to-curb, or be cut back at the sides to allow bicycles to pass and facilitate drainage. Notable speed reductions occur within 60 m (200 feet) of the speed hump, both downstream and upstream. A single Watts' hump reduces vehicle speeds to the range of 25–30 km/h (15–20 mph) at the hump. Vehicle speed increases at a rate of approximately 1 km/h (0.5–1 mph) for every 30 m (100 feet) outside of the 60-m (200-foot) approach and exit. This type of speed hump is considered appropriate if the posted speed limit is 50 km/h (30 mph) or lower (per ITE Guidelines for the Design and Application of Speed Humps), though some suggest a speed limit of 40 km/h (25 mph) as the maximum value. Speed humps in the United States are not considered appropriate if the 85th percentile speed prior to implementation is 45 mph or more. If the objective is a point speed control, then only a single hump is required. A series of humps are usually needed to reduce speeds along an extended section. Typically, speed humps are spaced at between 100 and 200 m (300 and 600 feet) apart. In many jurisdictions, speed humps are marked, and painted with white stripes to be noticed by drivers. In some countries, notably Norway, the preference is to have the speed hump blend with the pavement color and only advise drivers at the beginning of a street that there are speed humps. The idea is that drivers will not increase speeds as much in between the humps when they cannot easily see where the next hump is. Speed humps are low-cost measures with low maintenance. The typical cost of deployment of a speed hump ranges from \$2000 to \$4000.

Speed Bumps

A speed bump is similar to a speed hump but much shorter in direction of travel. A typical speed bump is 8–15 cm (3–6 inches) high and 0.3–1 (1–3 feet) long. Like speed humps, speed bumps extend transversely across the roadway. Due to their lower breadth, they cause higher discomfort to motorists than speed humps traversing them at speeds up to about 25 km/h (15 mph) and generally results in vehicles slowing to 8 km/h (5 mph) or less at each bump. However, if they are traversed at speeds above 50 km/h (30 mph), they do not cause any discomfort but may damage the suspension of a vehicle. Due to their lack of efficiency in reducing higher speeds, and extreme discomfort at modest speeds, they are not typically deployed on public roads but are often used on private property, such as parking lots, private streets, and within apartment complexes. The effect on driver speed is similar to the effect imposed by speed humps. Like speed humps, to reduce speeds along an extended section of the street, a series of bumps are usually needed, generally spaced between 100 and 200 m (300 and 600 feet) apart. Like a speed hump, a speed bump also is a low-cost measure with low maintenance. The typical cost of deployment per speed bump is very close to that of speed humps.

Speed Cushions

Speed cushions are modifications of speed humps. One of the significant drawbacks of speed humps is that they increase emergency response times. Speed cushions address this concern by allowing passages of larger vehicles without any vertical deflection. The primary difference is that a speed cushion has wheel cutout between the raised areas to enable a vehicle with a wide track, such as emergency response vehicles and buses to pass through without much discomfort. While most dimensions are similar to speed humps, it is common to design the top of speed cushion to be level, as opposed to parabolic or circular for speed humps. This is preferred on primary emergency routes or along transit routes with frequent service. The overall effectiveness of speed cushions is similar to that of speed humps. Therefore, spacing and other design specifications are the same as those recommended for speed humps. Speed cushion is a low-cost measure with low maintenance. The typical cost of deployment of a speed cushion ranges between \$2500 and \$6000, slightly more than the cost of a speed hump since it requires more material than a speed hump.

Speed Tables

Speed tables are another version of speed humps. The major difference is that the top of the speed table is flat instead of parabolic. Speed tables are typically used to slow drivers in the middle section of a city block or on approaches to multilane roundabouts. They are usually longer than speed humps, with a height of 7.5–10 cm (3–4 inches) and a length of about 7 m (22 feet). Slopes should not exceed 1:10 at entry and less steep than 1:25 at exit. Side slopes on tapers should be no steeper than 1:6. The most common speed table consists of a 3-m (10-foot) plateau with 2-m (6-foot) approaches on either side, which can be straight, parabolic, or sinusoidal in profile. Speed tables are not recommended on streets wider than 15 m (50 feet). Speed tables are typically paved using distinctive material, both in structure and in colors, such as brickwork, to attract driver and pedestrian attention. A single speed table can reduce 85th percentile speeds to a range of 40–55 km/h (25–35 mph), though the effect declines at a rate of approximately 1–1.5 km/h (0.5–1 mph) for every 30 m (100 feet) beyond the 200-foot approach and exit. Like speed humps, speed tables in the United States are not considered appropriate if the 85th percentile speed prior to implementation is 70 km/h (45 mph) or more. Compared to this practice, in northern Europe, crosswalks are not used if the speed limit is above 80 km/h (50 mph), and not recommended unless the

speed limit and actual speed are below 40 km/h (25 mph) and speed tables would typically not be used unless there are crosswalks. This means that if the 85th percentile was 70 km/h (45 mph), it would have to be reduced to below 50 km/h (30 mph) using speed tables or other devices. A speed table is considered as a medium-cost measure with a typical cost of deployment ranging between \$2500 and \$8000. The additional cost is due to the requirement for more materials.

Raised Crosswalk

Raised crosswalks are an extension of speed tables when placed near a mid-block pedestrian crossing. The breadth of the raised crosswalk remains the same as that of speed tables, but in most cases, they are slightly higher, with a height of 8–15 cm (3–6 inches) above street level, so that the top aligns with sidewalks. While all other design elements remain the same, raised crosswalks also require all of the standard crosswalk design elements, such as signs and markings. The effectiveness in speed reduction is very similar to that of speed tables. To make raised crosswalks pedestrian-friendly, they are often deployed in conjunction with curb extensions, which are discussed later in this paper. Raised crosswalk is considered as a medium-cost measure with a typical cost of deployment ranging between \$4000 and \$8000.

Raised Intersection

Raised intersections are another extension of speed tables. They are employed when speeds need to be reduced on two intersecting streets. Raised intersections have ramps on all approaches, leading to a flat, raised area that covers entire intersections. Like a raised crosswalk, a raised intersection typically rises to sidewalk level. They improve pedestrian safety at busy intersections and are often found in commercial business centers and residential areas. Like speed tables, raised intersections are typically paved with distinctive material. Raised intersections are appropriate on streets with a speed limit of 30 mph. The raised intersection is considered as a high-cost measure with a typical cost of deployment ranging between \$15,000 and \$60,000.

Traffic Calming Devices With Horizontal Deflections or Narrowing

Traffic calming devices with vertical deflections are effective at reducing speeds, but they are highly inconvenient to drivers and cause problematic discomfort for individuals with health concerns, such as elderly or disabled people. Horizontal deflections or narrowing can address these concerns. Horizontal deflections reduce speed by forcing vehicles to swerve slightly, while narrowing reduces the priority given to vehicles by limiting roadway area. This category of speed reduction techniques includes any technique that reduces the area of a street designated exclusively for motor vehicle travel. The additional reclaimed space is typically used to improve safety or attract other modes of transportation, primarily pedestrians. Commonly used techniques are curb extensions, chicanes, lateral shifts, curb radius reductions, lane narrowing, on-street parking, raised medians, and road diets. Some of the commonly used ones are discussed as follows.

Curb Extension

Curb extensions visually and physically narrow the roadway, creating safer and shorter crossings for pedestrians and increasing street-side space for public features, such as benches, shrubs, and trees. They are most often used in downtown neighborhoods and residential streets. Curb extension is an umbrella term that encompasses several different treatments and applications. Mid-block curb extensions, known as pinch points or chokers, may include a cut-through for bicyclists. Curb extensions used as gateways to minor streets are known as neckdowns. While design speed limit varies concerning the dimension and width of roadway, curb extensions in the United States are typically used on roads with speed limits of 55 km/h (35 mph) or less. Curb extension is considered as a medium-cost measure with a typical cost of deployment ranging between \$8,000 and \$12,000. However, sometimes they can cost over \$40,000 if drainage alteration is required. Curb extensions can be combined with raised medians (see later) and if the distance between the curbs is not more than 2.4 m (8 feet), they have the added benefit of slowing down traffic significantly. In London, England, spacing of 2.1 m (7 feet) giving speed around 5 km/h (3 mph) has been used at entries to intersections but then fire trucks and other wide vehicles need to use the exit side to get into the intersection which could cause head-on collisions.

Chicanes

Chicanes are speed-calming devices that sharply alter horizontal alignment over a small distance, forcing motorists to steer back and forth out of a straight travel path. Generally, chicanes are created of curb extensions that alternate from one side of the street to the other. Sometimes, on-street parking is used instead, but it may not be as effective when no vehicles are parked due to the lack of a physical imposition. A shift of one lane's width or a deflection angle of at least 45 degree is recommended to prevent drivers from maintaining their speed and alignment. For a given length of the chicane segment, as the deflection angle increases further, drivers are forced to reduce speeds further. Chicanes are appropriate for streets with a maximum speed limit of 55 km/h (35 mph). They are typically not necessary along primary access routes to commercial or industrial sites. Chicane is considered as a medium- to high-cost measure with a typical cost of deployment ranging between \$8,000 and \$25,000.

Lateral Shift

A lateral shift is the realignment of an otherwise straight street that causes travel lanes to shift in one direction. A typical lateral shift separates opposing traffic through the shift with the aid of a median. Without medians, drivers can cross centerlines to achieve the straightest possible path, thereby eliminating the need to reduce speeds. Medians also reduce the likelihood that motorists will veer

into oncoming traffic, further improving roadway safety. Typically, a lateral shift is deployed in conjunction with on-street parking. Similar to chicanes, lateral shifts are appropriate for streets with a maximum speed limit of 35 mph, but not along primary access routes to commercial or industrial sites. Lateral shift is considered as a medium- to high-cost measure with a typical cost of deployment ranging between \$8,000 and \$25,000.

Curb Radius Reduction

A wide curb radius at intersections typically results in rapid turning movements by motorists. By reducing the curb radius and causing tighter turns, drivers must reduce their right-hand turning speeds to below 20 km/h (12 mph). This also limits crossing distances for pedestrians. While standard curb radii are 3–4.5 m (10–15 feet), many cities use corner radii as small as 60 cm (2 feet) because of the high volume of vehicle and pedestrian traffic. A curb radius of 60 cm (2 feet) causes drivers to reduce their turning speed to less than 15 km/h (10 mph). However, this technique is not suitable in areas with a large number of turning trucks or buses, since raised aprons would be needed and pedestrians may get in conflict with trucks if standing on the apron. The cost of deployment of this measure varies significantly between \$2,000 and \$20,000 per site based on site condition.

Lane Narrowing

Wide streets encourage speeding, especially during off-peak hours, which makes lane narrowing an attractive technique. Studies have shown that a 30-cm (1-foot) lane reduction can reduce average speeds by as much as 1.6 km/h (1 mph), but it can also increase the number of collisions by 3%–5%. Therefore, lane narrowing should be implemented with caution and primarily only on streets with one lane in each direction and ideally only when there is a continuous raised median. This is one of the measures with a wide range of costs. The cost of deployment varies significantly, depending on various factors. For example, adding striped shoulders will cost only about \$1,000 per mile, whereas adding on-street parking, in addition to adding a striped bike lane, will cost between \$5,000 and \$10,000 per mile, depending on the number of lanes to be removed. If constructing physical infrastructure such as raised medians or improvement of sidewalks are included, the cost can go \$100,000 or more per mile.

On-Street Parking

On-street parking reduces available lane widths. This reduction in lane width reduces speeds by adding side friction to the traffic flow. On-street parking can be located on one or both sides of a roadway and can be located on alternating sides to create a chicane effect, as previously discussed. The result can be a speed reduction of 1.6–8 km/h (1–5 mph), with a reduction of 3–5 km/h (2–3 mph) being the most common. However, on-street parking poses serious safety concerns for pedestrians entering and exiting their vehicles. On-street parking is a low-cost measure. The cost of deployment of an on-street parking scheme varies depending on the length of applications and design specification. However, the typical cost of deployment is less than \$6000 for parallel parking. If diagonal parking is used, it should be of back-in, drive-out type.

Raised Medians

A raised median creates a barrier between opposing lanes of traffic. While raised medians reduce lane width and thereby reduce driver speed, they also provide other benefits, such as the lower risk of head-on collisions and the opportunity to create protected pedestrian refuges in the middle of crosswalks. The raised median is considered as a low- to medium-cost measure with a typical cost of deployment ranging between \$1,500 and \$10,000, depending on the length and width of islands.

Road Diet

Road diets have been described as “removing travel lanes from a roadway and utilizing the space for other uses and travel modes.” For example, the conversion of an undivided four-lane roadway into an undivided three-lane roadway made up of two unidirectional lanes, and one two-way left-turn lane would cause drivers to reduce their speed. The reduction of lanes can also be used for other purposes, such as bike lanes, pedestrian refuge islands, public transit, and on-street parking. A road diet is considered as a low-cost measure. Although the cost of deployment of a road diet scheme varies depending on the geometric changes and length of applications, the typical cost of deployment is less than \$6000.

Roundabouts

Single-lane roundabouts with good designs reduce 85th percentile speeds to 27 km/h (17 mph). Multilane roundabouts often need to be combined with speed humps or speed table to reduce top speeds to anything below 40 km/h (25 mph) during low-volume times when drivers can straddle lanes; but even that is a lower speed than typical at many traffic signals. Roundabouts can be used even if there is very little cross-traffic but motorists prefer them at busy locations where they not only slow down traffic, but also typically reduce average travel times significantly compared to signalization.

Other Infrastructure Improvements

In addition to traditional traffic calming measures such as vertical and horizontal deflections, there are other tools to reduce speeds. However, most have a limited effect and are, therefore, not discussed in detail. Two established tools are surface treatment and pavement markings.

Surface Treatment

Studies have shown that by changing the surface texture, speed can be reduced. Textured crosswalks and textured pavement are somewhat frequently adopted on urban streets with speed limits below 55 km/h (35 mph) with the aim of promoting nonmotorized activities. Transverse rumble strips that cause vehicles to vibrate are used on freeways and other high-speed facilities to warn drivers of impending speed limit reductions or toll plazas. Unfortunately, the implementation and maintenance of surface treatments can be costly and, like vertical deflections, may cause problematic discomfort for elderly and disabled people.

Pavement Markings

Pavement markings provide visual cues to reduce speed. Examples include converging chevrons, dragon teeth, full-lane transverse bars, on-road “signs,” and peripheral transverse bars. Studies have shown mixed effectiveness that is highly site-specific. Pavement markings are considered as a low-cost measure, although it requires regular maintenance. The cost of deployment of pavement markings varies depending on the type of application and design specification. However, the typical cost of deployment is less than \$6000.

Behavioral-Based Measures

As the name suggests, this category of interventions tries to achieve the desired speeds by influencing driving behavior. Examples include education and enforcement measures. Enforcement has shown a significant impact on speed reduction. These include manual enforcement or automated enforcement. Manual enforcement is costly, and it will lose its effects within a few days of completion unless regularly repeated. Therefore, automated enforcement is a better option, especially if it is area wide, for example, measuring the average speed between two adjacent cameras, see Article 10167, Photo/Video Traffic Enforcement. Education/awareness can also play a role in speed reduction at least if people’s attitudes are modified, see Article 10128, Education and Training of Drivers. In addition to media campaigns, measures such as speed trailers have shown to help reduce speeds, at least among drivers who were unaware that they were speeding, especially on low-speed facilities. Other than the traditional driver educational programs and enforcement initiatives, deployment of tools such as cameras automated enforcement and portable speed trailers to alter driver behavior have also shown short-term effectiveness in reducing speeds. The cost of educational and enforcement campaigns depends on the duration and details of campaigns. However, a typical speed trailer cost between \$8,000 and \$20,000 depending on the available messaging options. The speed cameras that are used extensively all over Sweden cost about \$45,000 each to install and then have operational costs as well.

Emerging Technologies and Measures

Recent technological advances, especially in sensors, are beginning to allow for traffic safety innovations. Some emerging technologies include active bumps, GPS-based speed governors, and mid-block traffic signals with speed detection.

Active Vertical Deflections

As discussed in the previous section, measures with vertical deflections such as speed humps are incredibly useful in reducing speeds. However, they are not popular due to the discomfort they cause even at low speeds. One way to address this issue is to develop active vertical deflections. These devices use sensors such as radars or on-road sensors to detect the speed of oncoming vehicles and activate the deflections only if the approach speed exceeds the posted speed limit. There are a few of these measures that are in conceptual or deployment stages. Some of the examples include Edeva, Smart Bumps, and Dynamic Rumble Strip System. Edeva is a trapdoor bump that raises for speeders (Edeva, 2019). Smart Bumps are angled vertical deflections that adjust based on driver speed (Smartbumps, 2019). Dynamic Rumble Strip System helps to alert the drivers when they pass this at high speeds using a set of closely placed trapdoor bumps with smaller widths (Paz, 2018). It is important to keep in mind that the capital costs of these devices would be high and would require electricity to operate. Also, since these tools use sensors, they require regular maintenance. In spite of these drawbacks, they offer a serious prospect to address some of the challenges that traditional traffic calming devices pose. While there is little field evidence to evaluate their effectiveness, active vertical deflections have the potential to offer results that are similar to their counterparts without actuation.

GPS-Based Speed Governors

Speed governors are physical devices used to measure and regulate vehicle speed. Governors have been in use for several decades, mainly on commercial vehicles. The devices prevent drivers from exceeding a set maximum, usually 105 km/h (65 mph). Such governors are mandated on trucks in much of the EU and in several Canadian provinces. However, most governors currently allow for only a one-speed setting. GPS-based speed governors, a recent innovation, adjust the maximum speed based upon the posted speed limit. Currently (May 2019), there is a proposed plan in Europe backed by Members of the European Parliament and the European Transport and Safety Council to introduce mandatory GPS speed limiters on new model vehicles starting May 2022 and on

new face-lifted models starting May 2024. It has been estimated that this system will reduce collisions by 30% and save 25,000 lives within 15 years of being introduced.

Mid-Block Traffic Signals With Speed Detection

This is an innovative signal that has been in use in the United Kingdom. Mid-block traffic signals remain green until a pedestrian activates them or until a vehicle approaches at speed 8 km/h (5 mph) or more above the posted limit, forcing drivers to stop completely. These devices, combined with red-light running cameras, have the potential to be highly effective in reducing vehicle speeds.

Since the measures discussed under this section are not yet available for commercial deployment, the costs of these measures are not readily available.

Accommodating Nonmotorized Users

As the primary objective of speed-reducing measures is enhanced safety of all road users, these are extensively used on residential roads, in school zones, and where high nonmotorized activities are expected. The level of haptic feedback and ideal operating speed depends on the type of traffic calming device deployed and its design. The human body can accept vibration energy up to a certain level above that repeated exposures pose a health hazard. Since most of the bicycles do not have proper suspension systems, a study by Patel and Vasudevan (2016) concludes that bicyclists experience higher levels of discomfort than those experienced by motorized vehicles while passing over speed-reducing measures with vertical deflections. The same would be true with altering surface types. Since traffic-calming measures with horizontal deflections do not induce vibrations, these would be appropriate in locations where high bicycle activities are expected so that these devices are not producing unintended consequences. Roundabouts are not nonmotorized user-friendly since the crossing facilities are placed away from the roundabout. Therefore, in areas where pedestrian presence is high, roundabouts are not recommended. Also, it is worth noting that the measures with horizontal deflections may not be as effective in reducing speeds when compared with the ones with vertical deflections. Therefore, choosing the right type of traffic calming measure requires a fine balancing of these two contradicting properties based on the site-specific requirements.

Overview

Traffic signs and striping are essential to highway and street designs and operations. They are commonly utilized to communicate with road users. Appropriate installation of striping and signs contribute to improved road safety and mobility along a roadway. This chapter describes typical applications of striping and signs, along with their safety benefits. Relevant issues from road safety perspective are also discussed.

At present, several countries have adopted the Vienna Convention on Road Signs and Signals, while traffic engineers and transportation planners in the United States (US) consider guidelines such as the Manual on Uniform Traffic Control Devices (MUTCD) in designing and selecting appropriate traffic signs and control devices for their road network. According to MUTCD, a traffic control device is defined as “a sign, signal, marking, or other device used to regulate, warn, or guide traffic, placed on, over, or adjacent to a street, highway, private road open to public travel, pedestrian facility, or shared-use path by authority of a public agency or official having jurisdiction, or, in the case of a private road open to public travel, by authority of the private owner or private official having jurisdiction (FHWA, 2009).”

In principle, traffic signs can be categorized into three groups serving three distinct functions, that is, regulatory signs, warning signs, and guide signs. Regulatory signs are used for statutory requirements according to traffic law and regulation, while warning signs alert drivers to hazardous or potentially hazardous situation that might not be easily apparent. The guide signs are typically aimed to provide relevant information on the directions or information specific to destinations or points of interest. Traffic signs are varied in dimension, symbol, color, and size. **Table 1** presents examples of traffic signs commonly found along roadways.

Road striping and lane marking is normally used to delineate a roadway path and separate traffic movements in either the same or opposing directions. A proper installation of road striping and lane marking can reduce several crash type risks, particularly sideswipe, head-on, and run-off road crashes. The effectiveness of striping is enhanced for people driving vehicles with lane departure alert systems. Striping can also be used to warn drivers of potential hazards ahead or conflict points along the roadway. Other applications include Chevron markings and word markings, such as STOP AHEAD. Rumble strips and audio tactile line markings differ from other signage and lane markings in way that they provide not only visual information but also vibratory and audible warnings. **Table 2** illustrates various types of road striping and pavement markings. All longitudinal, transverse, and other markings are common and are designed to provide drivers information necessary for efficient and safe driving.

Applications

The primary purpose of traffic signs is to regulate, warn, or guide road users along the roadway. Failure to comply with traffic control devices could lead road users to be fined as well as have crashes that may cause injuries and even death. In general, drivers are required to follow local traffic laws and regulations, which are frequently posted on regulatory traffic signs such as speed limit, travel direction, and restriction of certain vehicle types on the road. Likewise, warning signs are utilized to warn road users about approaching situations on the road such as changes in road geometry or risk conditions in the surrounding area. A proper warning sign should inform drivers that they can safely maneuver their vehicles to intended destination and avoid confusion at any conflict

Table 1 Types of traffic signs

Category	Examples	Typical sign sheets
Regulatory sign	Stop, yield/give way, speed limit, One way, No parking, Do not enter	
Warning sign	Intersection warning, School zone warning, Crossings, Slippery when wet, Speed bump	
Guide sign	City/Town name, Route/Highway number, Destination and distance	

Table 2 Types of road striping and pavement markings

Category	Examples
Striping/longitudinal line marking	Center lines, lane lines, edge lines
Pavement marking	Stop bars, crosswalks, arrows
Others	Chevron marking, Rumble strips, audio tactile line markings, word markings

points such as intersections or crossroads. Ideally, warning signs should be displayed only during the times when they are needed. For example, warning drivers of freezing roadways at bridges during summer-weather conditions makes little sense.

From the MUTCD guidelines, traffic control devices should fulfill a need, command attention, convey a clear, simple meaning, command respect from road users, and give adequate time for proper response. Therefore, traffic engineers should carefully select relevant types of traffic signs and information. However, in many jurisdictions that is not the case. For example, in many US states, stop signs are frequently used at intersections where fewer than 20% of drivers come to a full stop and a sizable percentage of drivers do not even slow down. Stop signs are still used because they supposedly send a message to drivers that they do not have the right-of-way at that location and need to yield to other traffic; and many drivers do not seem to understand that a yield sign could convey that information. But if stop signs are not respected at most locations, installing a stop sign where a full stop is needed will not have the intended safety effect. **Fig. 1** illustrates various road settings in some selected countries showing traffic signs and road striping.

The treatment of traffic signs on the road can be affected by several factors, including facility type, traffic volume, and characteristics, as well as economic benefit and cost consideration. A conventional octagonal stop sign, for example, is in the United States

(A) Australia

(B) Japan

(C) Russia

(D) Thailand

Figure 1 Various road settings showing traffic signs and road striping.

normally recommended on a minor road entering a designated through highway with traffic volume greater than 6000 vehicles per day. Alternatively, MUTCD states that the stop sign can also be considered when there exists a strong evidence of historical crash records particularly right-angle crashes from drivers on the minor-street approach. If this rule was followed, we may get more respect for stop signs than following the current prevailing practice—in most US states—to put stop signs at every intersection.

Placement of traffic signs also directly influences visibility of road users. Therefore, the minimum required visibility distance should be justified. Such a distance is a function of speed and depends on type of traffic sign. As an example, an intersection warning sign should be placed in advance of the approaching intersection, and the advance placement distance should, according to MUTCD, be computed based on the 85th percentile speed and suitable sign legibility distance. Placement of warning signs should also reflect the perception-response time (PRT) to ensure that drivers have adequate time to detect, comprehend, and respond to traffic signs safely.

The main purpose of road striping and pavement markings is to specify the designated maneuvering area of road users and to guide them in the direction of travel ahead. In addition, striping and markings provide guidance and warning to road users in terms of road rules such as lane changing, overtaking, and intersection crossing, as well as merging into a traffic stream. Road striping and pavement markings may also reduce crash risks and increase mobility associated with poor visibility. One hypothesis states that with appropriate road striping, drivers who maneuver during inclement weather or darkness could safely judge the alignment of the road and avoid being involved in crashes. In reality though, many studies show that nighttime crashes go up as a result of better lane guidance since it leads to people driving faster and they still do not see pedestrians, animals, and crossing traffic at any further distance than they would without that guidance.

Striping is commonly applied to designate travel lanes, showing desired path and direction of travel. A typical road has edge line striping that delineates the left or right edge of a traveled way. Edge line striping can also be considered for roadways with different usages such as pedestrian walkway and bicycle facility. However, it needs to be remembered that striping by itself gives very little protection in separating such road users from automobiles. For shared-use paths or undivided roads, centerline striping can be seen as a type of median. Again, it has to be stressed that a stripe by itself does not guarantee that drivers do not cross over it.

In addition to providing road users information for maneuvering on a road, striping and pavement signs provide potential benefits in terms of road safety, not only to drivers but also to vulnerable road users such as pedestrians and bicyclists if they have to share the road facility. Edge striping without the striping of centerlines can be used to slow down motorists if one makes the travel roadway very narrow, say around 6 m. This should only be used in urban areas with speeds of 40 km/h or less. Without the

centerline, motorists fear that they may have a head-on collision and will slow down significantly whenever there is oncoming traffic. However, this will only work if they cannot encroach onto the edge stripes, so the edge stripes need to be complemented with vertical delineators. Uncomfortable rumble strips can also be used to achieve this effect but have the disadvantage of creating noise, which may be unacceptable in residential areas.

Striping and pavement markings can be installed by several materials such as paint, thermoplastic, or pre-cut sheeting. Different patterns and colors of striping and pavement markings denote different communication messages to road users. For instance, a solid continuous white line striping indicates in the United States the edge of the roadway, while a broken white line striping separates travel lane in the same travel direction and that road users may cross this line when changing lanes. Similarly, double yellow lines in the United States prohibit passing in either direction unless it is the passing of a bicyclist or pedestrian whereas making a left turn across it into a driveway is permitted. On the other hand, a double solid white or yellow line in many European countries means that it is illegal to cross the line for passing or making a left turn. Application of striping and pavement markings today follow local guidelines and standards to ensure that road users can perceive and comprehend correctly and perform reasonably safe driving accordingly. It probably would be better if we had international standards so that striping gave the same message everywhere so that tourists and other visitors understand the meaning.

Safety Benefits

Information that drivers receive from properly installed and displayed striping and traffic signs help them make informed decisions on how to maneuver their vehicles safely under prevalent roadway and traffic conditions. Although there are only limited past studies showing tangible benefits in terms of crash risk reduction after striping or typical traffic signs are installed, it is widely accepted as being beneficial to road users and critical to a safe road design and standards. And, surveys of drivers indicate that improved striping belong among the most popular measures a road administration can undertake to please its drivers. Benefits of traffic signs are more profound for drivers approaching difficult driving tasks such as ahead of a complex curve, in bottleneck locations, or in an area where operating speed should be substantially reduced due to sudden change in road geometry or roadside environment. Under these circumstances, provision of warning traffic signs would potentially reduce severities and number of crashes and thus make the road safer. However, drivers often ignore such warning signs, and compound curves on highway ramps that start out with a gentle curve and then transitions into a sharp curve often see many crashes even after large chevron signs are erected. Changing the roadway geometry and making the curve gentler, or at least using a constant radius and having drivers see the curvature of the ramp before they enter the curve—so called self-explaining roads—may be more effective than signage.

For striping and pavement markings, centerline and edge line markings can be regarded as a low-to-moderate cost treatment that provides some crash reduction potentials, especially in situations with complex geometry. Additional benefit can be gained in certain road types. For instance, a high-speed, two-way undivided rural road with clear centerline markings may have a lower likelihood of head-on crashes than an unmarked roadway. However, installing centerline rumble strips cut fatalities from head-on collisions with opposing vehicles to roughly half of what is experienced with good striping alone, and installing cable barriers in the center of the road cuts most of the remaining ones.

A crash modification factor (CMF) is customarily utilized as a key effectiveness measure for selecting appropriate road safety treatments and countermeasures. By definition, the CMF is the ratio between the estimated number of crashes expected after implementing the road safety treatment and the estimated number of crashes without the treatment. A CMF value less than one indicates a sound treatment that is expected to reduce crash numbers. CMFs can be derived from a systematic before-after design, of which the safety performance of a group of locations is compared with the treatment of interest to similar locations without the treatment.

Table 3 lists potential crash effects for traffic sign installation based on the current Highway Safety Manual (AASHTO, 2014). Depending on type of setting and crash type, the CMF values for warning and speed sign treatments range from 0.54 to 0.87, signifying approximately 13%–46% reduction in estimated crash frequency after these measures are implemented.

It should be noted that the studies referenced for these effects were published in 1959 through 1971 and have been criticized for not accounting for regression-to-the-mean effects accurately. It would be useful if newer studies were conducted. Likewise, **Table 4** presents corresponding values for pavement markings, which range from 0.55 to 1.05. These CMF values may vary upon various circumstances and could only be used as a guideline for implementing road safety treatments in the study area. And it should also be

Table 3 Potential crash effects of treatments related to roadway signs

<i>Treatment</i>	<i>Setting</i>	<i>Crash type</i>	<i>CMF</i>	<i>s.d.</i>
Install combination horizontal alignment/advisory speed signs	Unspecified	All types (Injury)	0.87	0.09
Install changeable crash ahead warning signs	Urban (Freeways)	All types (Injury)	0.56	0.20
Install changeable “Queue Ahead” warning signs	Urban (Freeways)	Rear-end (Injury)	0.84	0.10
Install changeable speed warning signs for individual drivers	Unspecified	All types (All severities)	0.54	0.20

Table 4 Potential crash effects of treatments related to pavement markings

<i>Treatment</i>	<i>Setting</i>	<i>Crash type</i>	<i>CMF</i>	<i>s.d.</i>
Install post-mounted delineators	Rural (Two-lane undivided)	All types (Injury)	1.04	0.10
Place standard edge line marking	Rural (Two-lane)	All types (Injury)	0.97	0.04
Place wide (8 inches) edge line markings	Rural (Two-lane)	All types (Injury)	1.05	0.08
Place center line markings	Rural (Two-lane)	All types (Injury)	0.99	0.06
Place edge line and center line markings	Rural (Two-lane/Multilane undivided)	All types (Injury)	0.76	0.10
Install edge lines, center lines, and post-mounted delineators	Rural (Two-lane/Multilane undivided)	All types (Injury)	0.55	0.10

Source: AASHTO, 2014.

noted that the only studies referenced as giving a clearly positive effect with a CMF of 0.55 were published in 1968 and 1970, respectively (Roth, 1970; Tamburri et al., 1968). And the authors of the 1968 study, Tamburri, Hammer, Glennon and Lew, themselves writes on page 36 of the 1968 Highway Research Record Number 257, with respect to delineation that, “the findings are based on a relatively small number of locations and, in some cases, a small accident experience; thus, the representativeness of the data is open to question. Additionally, data on items most relevant to the issues being investigated were sometimes unavailable. Consequently, the findings are of a provisional nature (Tamburri et al., 1968).” It should also be noted that the authors use a simple before and after methodology not accounting for regression-to-the-mean effects. And they themselves conclude after finding that most of the striping combinations did not improve safety, “The findings are somewhat discouraging. Naturally, the hope was to demonstrate much more improvement than what appears to have been accomplished. It may be that the worth of delineation measures lie not so much in terms of accident reduction but in terms of “near misses” which might have been averted and the psychological comfort they may provide the driver.” It seems like newer studies of the effectiveness are warranted. The only other study referenced for the 0.55 CMF is a 1970 study by Roth (1970) at Michigan Department of State Highways. That study pertains to a 40-mile (64 km) section of rural freeway. And, the before and after study actually showed an increase in crashes after post-mounted delineators had been installed but less so than for control sections. So, to found the effect of “Installing edge lines, center lines, and post-mounted delineators” and give an expected CMF of 0.55 based on these two studies certainly seems to lack precision and lack a basis for generalization, or even application to our current roadway environment 50 years later.

A deeper discussion of the safety effects of edge lines and whether they are beneficial to safety can be found in Ezra Hauer’s book *Observational before-After Studies in Road Safety* (Hauer, 1993). He writes, “The painting of edge lines is often thought to enhance safety. However, the studies on which this belief is based are often seriously flawed.” He concludes that it is clear that they increase the feeling of safety but do not actually reduce accident risk.

The FHWA crash modification factors clearinghouse provides a web-based data source of various CMF values with supporting documentation for road safety-related activities.

The Handbook of Road Safety Measures (Elvik and Vaa, 2004), give similar effects. That book states that striping normal edge lines reduce crashes as well as injuries by about 3% whereas widening them from 10 to 20 cm increase injuries by about 5%. Striping of centerlines increases crashes by 1% but reduce injuries by 1%. Lane striping between parallel lanes seems to reduce crash numbers but the confidence interval for the measure spans from a 51% reduction to a 36% increase in crashes.

Alternatively, the iRAP Road Safety Toolkit provides proven road safety treatments in terms of their effectiveness and implement issues.

Issues to Consider

This section discusses several safety issues associated with these treatments.

Retroreflectivity

Retroreflectivity refers to the property of how light is reflected from a surface and returned to its source. A retroreflective traffic sign is one of the key factors that affect nighttime visibility, which can be obscured due to reduced illuminance. Road safety could be enhanced and some nighttime crashes could be prevented by making traffic signs appear brighter and easier to be detected at night. And road-user orientation can be improved at night and in the daytime by making them larger so they can be seen from further away leading to less abrupt changes in speed. Thus, road striping and traffic signs should be retroreflective and should be highly visible both in day and at night.

The retroreflectivity of striping and traffic signs can be measured by handheld devices or mobile devices and is typically determined by the coefficient of retroreflection (R_A), expressed in units of candelas per lux per square meter ($\text{cd lux}^{-1} \text{ m}^{-2}$). It is necessary that the coefficient of retroreflection meet the minimum level appropriate for a corresponding type of striping and traffic signs. Standards and guidelines for minimum retroreflectivity levels of traffic signs are generally set based on sign color and size, position of sign, and sheeting types, whereas those for longitudinal pavement markings are justified based on road type and posted speed.

Various retroreflective sheeting materials used in traffic signs provide different level of retroreflection and service life. They could be made with glass beads or micro-prism and range from engineer grade (ASTM Type I), high intensity grade (ASTM Type III), to diamond grade (ASTM Type XI). Many traffic signs follow standard specifications such as the ASTM D 4956-17 (standard specification for retroreflective sheeting for traffic control). Similarly, longitudinal pavement markings such as centerlines, lane lines, and edge lines are generally required to be retroreflective with a minimum maintained retroreflectivity levels. A well-maintained retroreflective pavement marking significantly helps drivers maintain their maneuver along designated paths and may prevent run-off road and head-on crashes particularly during the nighttime. However, they may also lead to higher travel speeds and whether the net safety effect is positive or negative seems to depend on the type of location.

Maintenance

Both traffic signs and striping should be periodically inspected and evaluated as they degrade over time. A systematic traffic sign inspection and inventory of traffic control devices should be maintained so that a replacement program can be effectively implemented before the end of their expected service life. The current MUTCD classifies maintenance of traffic signs and striping into two types, that is, functional maintenance and physical maintenance. The former action is to ensure that traffic signs and striping meet current traffic conditions, while the latter is to warrant legibility, visibility, and proper functions.

Activities such as sign cleaning and vegetation control can be performed as part of preventive maintenance. Damaged and faded traffic signs should be repaired or replaced. In addition, sign supports should be constantly monitored so that the sign crashworthiness is maintained. Maintenance priority is usually given to mandatory and warning signs on a roadway with higher functional classification.

Periodic measurement and evaluation of striping and road markings is necessary to ensure that they are legible to road users. Maintenance of striping and pavement markings can be performed mainly from two perspectives, that is, replacement based on monitored markings and blanket replacement. In the former situation, when the retroreflectivity level of a representative sample of markings that are monitored falls close or below the minimum acceptable value, pavement markings of similar kind are replaced. Alternatively, in the blanket replacement, pavement markings of the entire area or corridor are replaced when they reach their expected service life.

Redundant Signs and Striping

Traffic signs that are redundant could potentially reduce traffic safety and obscure visibility. In some situations, these signs are unauthorized and arbitrarily installed by other agencies, resulting in a visual pollution and overwhelming information to drivers. In addition, installation of too many traffic signs, especially at intersections, could distract drivers and lead them to undesirable driving decisions and behaviors such as sudden lane changing and dangerous overtaking. Therefore, a regular inspection should be conducted in order to spot and remove redundant or unnecessary traffic signs.

The sign redundancy issue is also related to modern advertising billboards, which are permitted in some jurisdictions. Those are often illuminated with high luminance in the roadside of urban areas. These billboards obviously distract visual attention of road users and can possibly lead to increased crash risks. The situation could be worsened at nighttime for a large digital light emitting diodes video billboard screen that are commonly found along the roadsides of some countries.

Redundant striping and pavement markings could result from road construction or road rehabilitation when temporary markings are installed and are not properly removed afterwards. Similarly, it could remain after new road surface treatments are installed due to changes in traffic conditions or road geometry. It is thus recommended that any temporary striping and pavement markings be removed to prevent road users from potential mislead or misdirect.

Human Factors

Although a road crash can be attributed to a combination of human errors, vehicle failure, and road hazards, the majority of road crashes can be influenced by human factors. Human factors deal with how drivers perceive road system, how they process the information, and how a decision is made. Understanding human factors help traffic engineers design a safe road system that can accommodate driver performance and ensure higher road safety. It is thus challenging for traffic engineers to incorporate road users' needs and design traffic components that are functional and relevant to all road user groups.

When operating a vehicle, reaction time can be considered as the combination of time required to see visual traffic signs (perception), identify traffic signs (identification), reach the decision (emotion), and execute the action (volition). Road users of different ages may maneuver and react differently on the road. Older and impaired drivers generally require more time to process information and respond to traffic signs and related information. Cross-cultural differences may also impact driving behaviors in various aspects, including reaction time, risk perception, risk-taking behavior, and general driving performance.

Uniformity

Uniformity of traffic signs and striping can facilitate driving tasks of road users. Many countries have adopted international standards, that is, the Vienna Convention on Road Signs and Signals for traffic control devices in order to facilitate international traffic movements. According to the Convention, road signs are classified into 8 categories from A to H, namely, danger warning signs, priority signs, prohibitory or restrictive signs, mandatory signs, special regulation signs, information, facilities, or service signs, direction, position, or indication sign, and additional panels.

Sometimes these standards and guidelines are adapted to local needs. Nevertheless, certain traffic signs and striping treating similar situation are yet found different in their shape, color, or size across countries. In locations with foreign driving travelers, unfamiliar traffic signs could be misinterpreted, and local traffic law and regulations could be unknowingly violated. In the worst-case scenario, falsely perceiving and interpreting traffic signs could result in crashes.

Nonuniformity issues can also be observed on various local traffic signs with local text or messages, causing foreign drivers to be unable or having difficulties to interpret the true meaning. Using symbols rather than words is therefore typically preferred. As an alternative in some countries, an English or other preferred second language text is additionally augmented on the traffic signs to facilitate international drivers. It is therefore important that all traffic signs and information be consistent in order to ensure that road users can correctly comprehend and perceive traffic signs, which could in turn reduce cognitive workload in driving.

Forgiving Devices and Self-Explaining Roads

Forgiving devices and self-explaining roads are the key concepts in safe system approach, a systematic approach that considers the holistic view of transport system management, including road infrastructure and facilities, road users, vehicles, and travel speed. The safe system principle essentially incorporates the notions of human fallibility and human vulnerability in creating a road system that is safe and forgiving for all types of road users with the main goal to reduce fatalities and serious injuries on the road.

Forgiving traffic control devices aim to strengthen road safety and minimize negative consequences due to human errors. Traffic signs could be equipped with breakaway supports that fail in a relatively safe manner when hit by a vehicle. In the United States, the AASHTO Manual for Assessing Hardware (MASH) presents a uniform guideline for evaluating highway safety features in terms of crashworthiness (AASHTO, 2016). Breakaway supports that are formally tested based on the guideline can be safely used on the roadside. Nonetheless, they should be avoided in certain circumstances where there is the possibility of having a secondary accident involving the impacting vehicle.

Self-explaining roads are designed such that drivers can clearly perceive the intended design and function of roads, and thus they immediately and instinctively know how to perform a safe maneuver according to the design. In such cases, roads must have a clear design that meets driver expectations. There are several ways to make a road self-explained. For instance, striping and pavement marking can be used in speed management by modifying lengths and spacing of centerlines. Treatments such as rumble strip on select road section can be used to gain attention of drivers. Similarly, audio-tactile line marking (ATLM) provides an audible sound and vibration when traversed by a vehicle, thus reducing the risk of head-on and run-off road crashes.

Concluding Remarks

Road striping and traffic signs are among the most fundamental and indispensable components in a roadway design. Drivers need to be informed about speed limits, hazards and regulations, and directional sign are needed to find one's destination. Drivers also often request improved striping and good striping definitely improves the perceived safety of a road. To provide better visual cues may also play a role in road safety but the effect is at best very modest. Road striping and traffic signs can influence vehicle operations to keep vehicles further apart and have people slow down earlier but they may at time also increase speeds. To maximize the benefits of striping and sign treatments, installation configuration should be congruent with the prevailing roadway and traffic conditions. In addition, historical crash records, if available, can be analyzed for potential locations that might lack appropriate installation of striping and traffic signs.

Several issues related to road safety, road striping and traffic signs are discussed in this chapter. Road striping and traffic signs should be designed such that they are self-explained and in line with other traffic control devices. Forgiving devices such as sign posts with breakable supports should be considered when applicable. During the operations phase, road striping and traffic signs should always be in good working condition, that is, they should be functional, legible, and properly placed at designated locations. During nighttime or inclement weather conditions, striping and signs should be retroreflective, clearly delineate the road path, and safely direct drivers to desired direction. Redundant striping and traffic signs should be removed or replaced to prevent potential conflicts and uncertainty to road users.

Selection of striping and traffic signs should be consistent and complied with standards and guidelines. Traffic signs that might confuse drivers and complicate driving tasks should be removed. Similarly, non-standard striping and traffic signs may be used with caution. Driver familiarity and human factors are among essential issues when placing striping and traffic signs on a road. Although a road agency may have its own standards and guidelines, it is important that road users of all types clearly understand their meaning. When foreign drivers are present, applying international standards with additional context that is universally understandable could be beneficial in comprehending traffic signs and the road environment.

In terms of maintenance, road striping and traffic signs should be periodically examined. Inspection should reflect changes in functional requirement on a timely basis. Non-functional and obsolete traffic signs should be removed, and faded road striping and lane markings should be repainted. Retroreflectivity of striping and traffic signs should be constantly monitored. A systematic inventory and maintenance program of road striping and traffic signs are thereby recommended. In many cases, advance traffic signs and pavement markings, incorporated with the intelligent transport system (ITS), could further enhance road safety. With the advent of ITS technologies, it is hoped that better and safer road systems can be achieved, and road traffic injuries can be minimized.

Introduction

Transport offers mobility over increasingly greater distances, catering for differing priorities of travelers, from relaxation and comfort through to enjoyment of a sense of speed in others. Sadly, as a result of speed, high mass and resulting impacts, a number of people take steps to end their lives in suicides involving transport. Some of these are a result of deliberate choices, though the extent to which the people involved are fully in control of their decisions and actions is debatable. We know that a proportion of suicide events are impulsive and can be influenced by a wide range of individual and situational factors.

Suicide is not easy to define (Silverman, 2016) and there are many definitions in the literature. Roughly one million people take their lives each year worldwide, with 10 times as many attempts (7.9 deaths per 100,000 population in China, 11.9 in the United Kingdom, 17.4 Australia, and 21.1 in the United States). Suicides are evident in all forms of transport: rail, road, aviation, and marine. These range from single person incidents on train tracks, in cars, from road bridges, and from ships, through to the extremely rare, but serious incidents like the decision of a pilot to crash a plane carrying many passengers. Data are identifiable to some extent in the classes within the WHO International Statistical Classification of Diseases and Related Health Problems (ICD-10 Codes), for example: X80 Intentional self-harm by jumping from a high place; X81 Intentional self-harm by jumping or lying before moving object; X82 Intentional self-harm by crashing of motor vehicle.

In this chapter, the focus is restricted to railway and highway (road) suicides. In both situations, these incidents result in death of the person involved, but can also include other consequences: the injury or death of others, psychological trauma for witnesses, relatives of the person and those involved in dealing with events and recovering bodies or body parts, and the economic costs of delay in dealing with incidents and getting road and rail networks back to normal operations.

The chapter includes an overview of what is known about suicides on railways and highways. This considers the incidence of these events from some of the available statistics, including commentary on the factors that can affect our understanding on the extent and nature of the problem in each of these transport contexts. Commentary is also provided on the current research directions and the initiatives that are being implemented in industry. In reflecting on where progress has been made in each area and some of the factors that hinder such progress, suggestions are made for cross-sector learning and priorities for future research and practice.

Railway Suicides

Statistics/Incidence

It can be hard to determine how many people take their lives on railways internationally. Statistics from around the world show some variation. Data from the United States shows 219–328 annual railway suicide fatalities in recent years, less than 1% of total suicides in the United States. There have been between 235 and 307 suicides in each of the last ten years on the mainline in Great Britain and London; underground system, equating to 3.6%–4.7% of the total number of suicides in Great Britain. More widely in Europe, there have been between 2756 and 2982 suicides on the railway annually, accounting for 73% of fatalities on European Union railways. These range from 0.4% of all suicides in Latvia to 13.0% of all suicides in the Netherlands (Reynders et al., 2011).

Statistics are also reported and compared by traffic density to account for differences in exposure. As examples, lower rates (0.2–0.3 per-million train kilometer) have been observed in Norway, the Republic of Ireland, and Greece and higher rates (1.2–1.4 per-million train kilometer) in Portugal, Czech Republic, and the Netherlands.

These statistics are informative, but there can be issues of misclassification, for a number of reasons, potentially impacting on cross-country comparisons. These include difficulties in interpreting what happened from the available evidence (often requiring open or narrative verdicts), differences in legal and reporting systems employed across countries, or the potential influence of religious or cultural factors in decision-making. There can be a time lag in making a determination of whether an event is suicide, such as, while awaiting a coroner verdict. This can introduce uncertainty into records and statistics of events over the most recent eighteen months. As a means of making judgments as early as possible, the industry in Great Britain apply the Ovenstone criteria (Ovenstone, 1972) in determining whether an incident is likely to be suicide, using a balance of probability judgment.

There have been many efforts to analyze various demographic, situational, and environmental factors associated with these events. These studies can provide useful descriptive evidence and can help target some preventative measures (e.g., campaigns aimed at higher risk groups, such as male, aged 40–60), though have lesser value in helping to predict where and when an incident may occur. On the whole, relatively small numbers of suicides are spread across the vast railway network, posing challenges to those who are trying to improve safety and reduce fatalities on the railway. It has been possible to identify some locations where there is a thought to be higher risk (usually determined by several incidents) and prevention can be targeted in these areas. However, it is difficult to say to what extent there may be common factors that connect a series of events at a particular location.

Types of Events

There have been various studies of the ways in which people take their life on the railway. Railways in some countries have high security and restriction of access to most areas of track. Therefore, the main access points can be at stations and railway crossings, with smaller numbers of people accessing the track over or through less substantial areas of fencing in various locations. In many countries the access is easier to unfenced areas of the railway (especially outside towns and cities). It is often thought that people choose locations where there are faster trains (e.g., outside of cities on the open line, on fast lines through stations where some trains do not stop at a station). As such, people may target a specific platform at a station, jump from the early part of the platform where train speeds are higher, find a point where they can hide to wait for a train out on the open line, or may move around the track area in search of a fast train. There are still many incidents involving slower trains, including freight trains, especially at night where there may be fewer passenger trains or in countries where the proportion of freight trains is greater (e.g., United States).

There have been efforts to classify the locations of incidents at a national level. In Great Britain, 50% of fatalities occur on the running line, 40% at stations, and the remainder at crossings or other locations. Different proportions can be seen in data from other countries. These national data tend to mask the true situation at a local level. In some areas (e.g., mainlines close to major cities), there may be very few crossings and access to the line is commonly from some point at the station. Consequently, the proportion of incidents at the station or near to the station will be much larger. Similarly, in a rural area, especially away from the main inter-city lines, the numbers of incidents at or close to a crossing are likely to increase.

There are also classifications of the mode of railway suicide (jumping, lying, wandering along or around the track, and touching electrical traction supply) (Ladwig et al., 2009). Recent work is collecting more detailed descriptions of the behaviors of the people prior to an event (Ryan, 2018), with the intention of refining efforts for prevention measures to respond to different types of incidents and access behavior. While there are greater proportions of these commonly reported modes of railway suicide, there are also smaller numbers of somewhat anomalous events (including driving onto railway crossings or unusual ways of making contact with a passing train), that need some consideration in the development of preventative measures.

Influencing Factors

Recent work in Great Britain (Marzano et al., 2019) is considering *Why people choose the railway for suicide?* This is thought to be because of ease of access, a perception of certainty of death, and death that is quick and painless. These can be misplaced perceptions and studies of data on suicides and suicide attempts indicate that up to 60% on metro systems and up to 90% of mainline rail attempts are successful. It is likely that some events are not the result of a planned and rational decision and can be impulsive. While it is known that there are some high-risk areas that are close to psychiatric institutions, many people involved are not known to be at risk by health services. People can reach a low point in their life, such that suicide seems a plausible way of escaping from the position in which they find themselves. This does not mean that they will continue to be suicidal or that they will move to another location if they are prevented from taking their life. Longitudinal studies of survivors of bridge jumps (Seiden, 1978) give support to the transitory nature of some suicidal thoughts and the long-term survival of those involved.

It is likely that aspects of the location can encourage the selection of a railway site for suicide. Sometimes this may be a prominent location, where there are frequent fast trains, with the ability to hide and not be disturbed and have seclusion from others. The intensity of train traffic and ease of access to the track are thought to be influencing factors (van Houwelingen et al., 2013). It is possible that some people don't think too hard about choice, but pick what is familiar or look for opportunities to access trains. Locations tend to be quite close to where people live. Knowledge of events at a location, or high profile events in the media can influence copycat incidents (known as the Werther effect, imitating the suicide of a hero from the work of Goethe) (Niederkrötenhaler et al., 2010).

Prevention

There are many available methods in operation across the world in efforts to prevent these types of events. There is still a gap in knowledge of what prevention measures work and in what circumstances. This is improving, but there is still a lot to do.

The classification of five overarching types of prevention methods ([Rådbo et al., 2008](#)) is a useful framework that provides an effective way of thinking about how a preventative initiative might operate in practice. These includes the following:

Reducing the perceived attractiveness and availability of rail traffic as a means of suicide. This reduces ideation, such that people don't associate the railway with a means of suicide. In practical terms this can mean responsible media reporting after an event, to minimize the risk of copycat incidents.

Limiting access to the track area or means of suicide. This can be achieved through fencing, though many practical difficulties can be anticipated. It is hard to fence all parts of the network, with particular weaknesses at stations and crossings. Platform edge screens have been tried with success in various underground systems, but preventing access is harder to do on mainline railways, where different train types and door configurations pose problems for alignment with openings in the screens. Through design of the infrastructure (station configurations, removing locations for hiding, effective use of lighting or auditory cues) it may be possible to influence how people move around a station and keep them away from places of risk.

Early warning to enable a fast response. Better understanding of behavior can be used in improving surveillance, either by people or technology. Regardless of how surveillance is carried out, there is a need for consideration of what type of response is needed and what is possible when someone is suspected of being at risk. This relies on having more informed staff and members of the public, with the confidence and willingness to intervene. There may be limited time in many cases to react, but in others there are indications of ambivalence and time to intervene as someone may be deliberating about their course of action. An example is the "Small talk saves lives" campaign in Great Britain, encouraging people to approach and talk with people who they suspect may be considering taking their life. This can also be in situations away from the railways. There is recent discussion in the literature of the Papageno effect ([Niederkrotenthaler et al., 2010](#)), where the likelihood of suicide can be reduced by the supportive intervention of friends.

Measures to persuade people to leave a place of danger. This has some links to effective surveillance, but could include interventions using traditional warning signs. More recent innovations include lighting or audible messages, triggered by sensors, to encourage people to leave the track area or place of hiding on a station platform, or to dissuade access to a tunnel on the rail network.

Measures to minimize the consequences of a collision. These are mitigating measures and are challenging in the railway context. Train drivers are relatively helpless to respond and unable to steer away from someone on the track, in a train that can take several kilometers to stop from high speeds. Such measures could include more responsive train braking and better design of train frontages to protect the people struck by the train. These have been considered historically (e.g., use of airbags and nets on trains), but often discounted for practical reasons. If progress could be made in this area of train design there could also be accompanying psychological effects on people contemplating suicide (i.e., by reducing suicide ideation, on account of the reduced likelihood of success of a suicidal attempt).

There has been much progress in recent years in collaboration between many organizations and agencies to improve understanding and share best practice in this area (e.g., infrastructure managers, train operating companies, transport police, local police, local authorities, and health authorities). There are excellent examples of working together at national and international levels. One example is the major collaborative EU project RESTRAIL, which included efforts to identify and evaluate the likely success of wide ranging preventative measures ([Ryan et al., 2018](#)), also including a series of pilot tests of recommended preventative measures. Collaboration is on going, with widening worldwide participation in the GRASP network.

Highway Suicides

Statistics/Incidence

Approximately 1.25 million people die on roads worldwide each year. Studies reported in the literature ([Pompili et al., 2012](#)), covering data from wide ranging international sources, suggest that between 1% and 7.4% of motor vehicles fatalities could be a result of suicide, though reaching as high as 10% in some years of study. Many of the studies focus on motor vehicle collisions and do not take account of vehicle–pedestrian collisions.

There are indications of under-reporting and misclassification ([Harrison, 2017](#); [Tøllefsen et al., 2015](#)), and this may be more problematic in highways than in the rail context, for a number of reasons (e.g., changes in data quality over time and exclusion of suicides from some reporting systems). Various recommendations have been made: for the need for education of crash investigators; improved awareness of medical staff; advice to coroners and researchers; better communication between authorities; better access to information for decision-makers in certifying deaths; and improved training of coders of national databases. In Sweden, there are efforts to ensure more in-depth study of incidents. This includes collection of more details on the vehicle, road and user (details of life events and mental and physical health—psychological autopsy), and uses input from experts from forensic medicine, psychology, and traffic safety backgrounds to classify fatalities as suicide or accidents.

Types of Events

Like railway suicides, these events include collision between a vehicle and pedestrian. These can also involve a driver (usually alone) steering into the path of another vehicle (often large) or fixed object (e.g., tree or structure). Other event types include driving into rail crossings (potentially with injury to the train driver and on-board passengers) or driving into water and subsequent drowning, or jumps of a pedestrian from height (e.g., road bridge). The relative frequencies of these different event types are not consistent in different studies across the world.

These incidents can include deaths of others (e.g., when in collision with another vehicle). It is thought that deaths of others can occur in as many as 11% of driver suicides. These impacts clearly add to the tragic circumstances, though it is possible that the people don't necessarily understand what they are doing or the consequences of their actions.

Determining intent can be difficult, especially within in-vehicle incidents. There may be evidence at the site (e.g., lack of skid marks, indications of high, uncontrolled vehicles speed, or limited efforts to avert collision), but these can also be indications of fatigue related accidents. Additional evidence is therefore needed from witnesses, relatives, autopsy, and police and coroners for correct classification of the event.

Influencing Factors

While not reported specifically in literature, some of the influencing factors in rail (individual, location, and environmental cues) are also plausible in highway contexts, by reason of similarities in the events. Seclusion is a factor in some incidents (e.g., one pedestrian and single occupants in vehicles). People may choose this method of suicide as it can be hard to be sure that this was in fact suicide and may protect families from the psychological trauma associated with knowing that they had chosen to take their life. Studies have indicated the influence of the Werther effect, where reporting of events can influence future events of a similar nature. Excess alcohol, drugs, extreme stress, and life events are thought to be factors, potentially making it easier to act impulsively. However, some prescribed drugs could impact on driver behavior and lead to car accidents, becoming confounding variables in analyses.

Prevention

Understanding the type of event and influencing factors are important in selecting the types of countermeasures that are likely to be effective for suicide. Generally, there are limited ideas in literature for prevention, with suggestions largely drawn from general road safety measures (Routley et al., 2003). For people in vehicles, these include design of the infrastructure (e.g., effective road side barriers) and crash protection in vehicles (e.g., technologies for automatic application of brakes, interlock systems to prevent driving while influenced by alcohol, prevention of tampering of vehicle safety features such as airbags, automated emergency call, and location indicator systems to help survival in the event of a crash). For pedestrians, suggestions include the design of cars to minimize impacts on pedestrians from collisions, better braking, and night vision systems. Some general principles are also reported, notably relating to the reduction of crashes and the energies involved in these. Other suggestions for suicide reduction include reducing heavy transport, better separation of heavy and light vehicles, better design of vehicle fronts (especially heavy vehicles), stability control, and enhanced braking systems in vehicles. There are few if any detailed studies in the published literature to evaluate the effectiveness of suggested preventative measures for highway suicide.

Comparing Railway and Road Suicides

There are many similarities in events across the two transport contexts, but also a number of differences of interest. Some of the incidents are similar in nature, involving pedestrians in collisions with vehicles, which are often large/heavy and fast vehicles. Similarly, jumping from bridges can occur onto railway lines or roads. Isolation is a common factor in each of these incident types and is evident in many events where people hide in secluded areas of stations or the track area, or near to roads or bridges. People are also alone in single vehicle incidents or single occupant vehicle collisions.

A wide variety of locations are possible in each of the railway and highway contexts. These are often easy to access (potentially easier on some highways than many parts of railways), with small numbers of events in any location and difficulties with prediction of location specific risk. Intervention is possible to prevent a suicide in some situations (e.g., where people may be waiting and visible in a location for a period of time before an event). However, events can occur with very little notice on the railway and highway, as someone emerges from a place of hiding, from close proximity to the line or road, or from the impulsive action of the individual. There is the potential for psychological trauma for any witnesses (train drivers, car/lorry/bus drivers) and staff involved in recovery. Events in both railway and highway settings cause serious disruption and associated costs for the industry and society as a whole.

A notable difference is that many of the suicides on highways occur within vehicles. These events are more likely to cause physical injury or death to others on road settings and it can be difficult determining intent and classifying these as suicides. As such, under-reporting of suicides is likely to be a greater problem in the highways context. In terms of prevention, it is very hard to intervene in these types of vehicle-to-vehicle collisions, as the first indication may be very close to the point of impact. Fencing and restricting access to the road network may also pose more difficulties than in railways. In contrast, some vehicle design mitigations are likely to have more potential for prevention in highways settings than in railways.

Future Directions—Research, Practice, and Policy

The number of suicides on the railways and highways are relatively low and a modest proportion of all suicides. However, these are very violent deaths, with far reaching impacts and trauma (mental and physical) to others, plus huge costs to the industry and society. In addition, the scale of the problem is not fully appreciated, with some underreporting, misclassification and delay in classification (i.e., a time lag in official statistics).

Better data are needed to understand the true scale of the problem, along with the circumstances surrounding the incident and the most appropriate approaches to prevention that are aligned with these circumstances. While compiling data at national levels and benchmarking these internationally can be informative, looking in detail at events at a local level is necessary to fully understand and design solutions for future prevention. Clarity is needed in several areas. Some of this information is collected by various agencies, but not shared very well and accessible to researchers and practitioners involved in prevention.

Detail on incidents. This can include firstly, the locations of incidents. Multiple reference points are relevant, such as, the access point, movements to locations around the track or road infrastructure, the final location of the event (e.g., line or part of carriageway). Location based findings can be specific to the particular incident or more generic lessons with wider application. Another consideration is the pre-incident behaviors of people involved. This can include gestures, movements, and interactions with others, potentially betraying an emotional state or intention. There are thought to be many successful outcomes from interventions from bystander campaigns. Improved knowledge in this area can improve training for staff, information for public awareness, and the future development and application of visual analytic surveillance systems.

Background of the people involved and the things that influenced them. There is an increasing awareness within organizations (railways and highways) and positive efforts and campaigns to reduce incidents. It is recognized by people in the industry that these events are not inevitable and things can be done to prevent them. This has not always been the case and within general society it is still possible to hear people say that these events cannot be prevented. People should not be treated as a homogenous group. There may be a proportion of people who will be determined and very difficult to influence, but there will be many who can, for a variety of reasons, be at a transitory low point in their lives and small interventions to prevent suicide can be successful.

It is necessary to continue efforts to improve understanding of preventative measures, in particular, which countermeasures work and in what circumstances do they work. In doing so, it is also important to consider how countermeasures are implemented and the extent to which they are implemented in the way in which they were intended. There are often gaps between the intention and what is actually implemented in a prevention program.

Evidence on the evaluation of countermeasures in the scientific literature is growing in railways, but there is still a lack of good evaluation studies. In comparison, there is very limited evidence in literature of testing of countermeasures for suicide in the highway sector. Some of the knowledge of railway safety interventions is held within industry and there were efforts to access this and determine consensus on the evidence in the RESTRAIL program (Ryan et al., 2018). This was an exercise that focused on immediate priorities for implementation within the RESTRAIL project and there are arguments for repeating this, with new terms of reference (e.g., considering more ambitious and novel interventions—possibly using cross-sector groups to share learning). This may need to contemplate major system change. As discussed earlier, some of these events are impulsive and can happen with apparent ease, with minimal opportunities to intervene. Looking back from a point in time in the future, what will we think of our history of unfenced platforms and vehicles approaching one another on single carriageways with high combined speeds?

In practice, countermeasures are often implemented in industry without any evaluation. Even where there is an appetite to evaluate, the knowledge of how to do this in real world settings is often lacking. This type of evaluation is difficult to do and even harder to roll out in a program across an industry. However, this doesn't mean we shouldn't try to improve the organizational/inter-organizational practices and processes that will support this type of work.

On balance, there seems to have been greater progress so far in railways, in terms of compiling knowledge of events, implementation and evaluation of prevention opportunities and collaboration between agencies (highways authorities, emergency services, health authorities, and voluntary sectors). Suicides are difficult problems to resolve, but there is value in any lives that can be saved with continued efforts in these transport contexts.

Biography

Dr. Brendan Ryan is an Associate Professor in the Human Factors Research Group at the University of Nottingham. He has wide-ranging experience in safety, accident investigation and ergonomics/human factors roles, predominantly in transport settings. This has included research on rail fatality prevention and management (suicide and trespass), with particular areas of interest on the study of behaviors of people before incidents and the implementation and evaluation of prevention measures. This has included the development of evaluation programs and support tools for industry, taking account of the challenges of implementing solutions and research findings in industrial contexts. Recent work has also included how this work can be applied in highways contexts.

Introduction

How to Measure Safety?

The number of road crashes or injuries that occurred during a certain time period and within a certain area seems intuitively like a good measure of safety, with a clear and direct relation to the core of (un)safety—human suffering and property harm. From a statistical perspective, the crash count is a random variable governed by some underlying distribution. For example, the annual number of reported crashes in a given area does not remain the same from 1 year to another, even if there are grounds to believe the traffic system has not changed particularly. It has also been shown on many occasions that naive comparisons of the crash counts without taking into considerations their random nature may yield very misleading results and such practice has been banned by the safety experts long ago. Safety is better measured by the number of crashes *expected* to occur in a given area and time period.

It follows that, since crash counts may only be used as a raw material for safety estimates, they are not as *direct* a measure as it may seem. In fact, there are several issues that make the use of crash records for safety analysis problematic and motivates the search for alternative (surrogate) measures with the same aim (estimation of the expected number of crashes):

- Road safety improvements and the constant decrease in crash numbers in most Western countries has a side effect of leaving safety experts with less and less data to work with. Once disaggregated by type or location, the numbers become so low that no statistically meaningful analysis can be performed.
- Collection of “enough” crashes usually require long time periods (at least several years). It is very unlikely that all the conditions remain constant during that time.
- Crashes are heavily under-reported in all countries, depending on the crash severity level, types of road users involved, location, etc. Vulnerable road users and particularly fall-related injuries seem to suffer highest under-reporting rate.
- The information available in a standard crash reporting protocol is scarce and biased by the witnesses’ and police officer’s opinions.
- Crash reporting is always a postobservation of the crash scene. Very little information is available about the process of crash development and dynamic factors present at that moment (such as another road user involved who avoided the collision and left the crash scene).
- The original purpose of calling police to a crash scene was to determine *whom to blame*. While this attitude is gradually changing towards the impartial collection of facts that can explain why the traffic system failed, the legal aspect of police work still has a great effect on the prioritization and search for evidence.
- Finally, there is an ethical dilemma in the reactive nature of the crash-based safety analysis. Before a verdict can be given, one must wait for unsafety to manifest itself in form of crashes and injuries.

As a result, the need for alternative proactive measures of safety has been advocated by traffic safety experts for a long time. The goal of this chapter is to give an overview of the state of the art in surrogate measures of safety (SMoS). This first section provides the core definitions and concepts, as well as a short historical perspective. Section “Operationalization of Surrogate Measures of Safety”

covers the methods to collect and use SMOs. The last section highlights where research is still needed and promising areas for the application of SMOs.

A Short Historical Perspective

The first documented attempt to assess safety by observing critical events in traffic is a study performed by a research laboratory of the General Motors company in the 1960s. The conflict definition covered nearly any action taken by a driver while approaching an intersection (activation of the light for braking or changing lane was used as conflict indicator) and the first results were inconclusive. However, the idea rapidly gained popularity, leading to the development of numerous conflict observation techniques in the 1970s.

These traffic conflict techniques (TCTs) used different indicators and protocols and it was hard to compare results and methodologies. As a response, The International Committee on TCTs (ICTCT) was created in 1977, an organization that had a significant impact on the development of the field in the coming years. ICTCT organized several workshops and joint calibration studies and developed solid theoretical grounds for the collection and interpretation of traffic conflicts. These activities are well-documented and, despite their age, still can be considered a must-read introduction to the subject (a library of essential reading is available at <http://www.ictct.net>).

During the 1980–90s, the TCTs got a solid reputation as a research method, but still were hardly used by traffic practitioners in their daily work. Among the reasons were the high reliance on human observers as the main data collection tool (together with doubts in objectivity of such a tool) as well as the high costs related to that. Starting from 2000s, however, automated and semiautomated tools for data collection, such as video analysis programs, became available and had a significant impact on the field. While not perfect and completely problem-free, automated tools opened for much more extensive data collection under longer periods and various conditions, and, what is important, for empirical tests and validations of various objective measures of safety.

Definition and Properties of Surrogate Measures of Safety

The SAE standard on SMOs uses the following working definition (SAE Committee on Surrogate Measures of Safety, 2019) (In the remainder, *interaction* is used as a synonym for *non-crash event*, referring to any situation where two road users, or one road user and an obstacle [or the side of the road for a road departure], are within perception distance of each other.):

“An indicator derived from the observation and the safety evaluation of non-crash events in traffic with the goal to estimate the expected crash/injury frequency as well as to get a better understanding of the crash mechanisms and contributing factors.”

This definition meets the following three conditions for a good SMOs slightly adapted from (Tarko, 2018; Tarko et al., 2009):

1. It properly captures the effect of changes to the traffic system.
2. It is associated (statistically) with the crashes affected by these changes.
3. It is practical.

The *validity* of SMOs is the degree to which it measures what it is supposed to measure, that is, road safety or, in practical terms the expected frequency of crashes (Laureshyn et al., 2016). While the ultimate goal is to have a clear and stable relation to the expected number of crashes expressed in mathematical terms, as of today the documented attempts to establish such relations are few and not always conclusive.

This strong form of validity is called *absolute product validity* (Laureshyn et al., 2016). When used to estimate the expected crash frequency, the surrogate measure should provide better accuracy than what can be obtained from standard traffic data like flow counts. In other words, it must be a measure of safety and not simply a surrogate for exposure. Yet, it is often sufficient to have an indication of whether the safety is improving or deteriorating, for example, to get a quick feedback after a change in road design or regulation, without knowing the actual scale of the change. This is called *relative product validity*, a lower degree of validity than absolute product validity (Laureshyn et al., 2016).

The second part of the SMOs definition refers to *process validity*, or the level of similarity in the underlying mechanisms of how the studied interactions and actual crashes develop (Laureshyn et al., 2016). This ensures that the crash mechanisms can be studied by observing the safety-relevant interactions. For example, if certain types of interactions seem to occur in certain conditions (e.g., approach at a high speed or at an angle affecting the field of view), the same contributing factors should be found in crashes of this type. Similarly, if a counter-measure affects these conditions and decreases the severity or frequency of relevant interactions, one should expect a reduction in crashes of the same type explained by the same causal mechanisms.

From a practical perspective, it is also important that:

- SMOs are based on interactions that occur considerably more frequently than crashes, so that observation periods are shorter;
- The definition of a specific SMOs is expressed in objective terms, so that it can be measured repeatedly and in an unambiguous way.

SMOs should be distinguished from other noncrash-based indicators used in safety work practice, such as “safety performance indicators” (seat-belt use, alcohol use, etc.) or behavioral indicators (yielding, head or gaze movements, etc.) that are explanatory factors to safety, but do not measure safety as such.

Figure 1 Examples of visual representations of the safety hierarchy as a pyramid (A) or a probability distribution (B) of interactions. *Source: Panel (A) adapted from Hydén, C. 1987. NCHRP 219, Midwest Research Institute.*

The Concept of Severity

The idea of SMOs rests on the assumption of a hierarchy and continuity among the events taking place on the road (**Fig. 1**). While crashes are the most severe interactions in traffic, and fatal ones the most severe among crashes, they are also the least frequent. At the other end are the least severe events representing normal traffic. Frequency is assumed to decrease as the severity, or nearness to a crash, increases. The research and development of TCTs relies on the assumption that the most severe interactions such as serious traffic conflicts defined in TCTs are the basis for valid SMOs ([Tarko, 2018](#)). Yet these may not be frequent enough to gather enough observations during a reasonable period of time and there are attempts at deriving SMOs from less severe, more frequent interactions ([Svensson, 1998](#)).

The concept of severity is related to the safety hierarchy of an interaction, as the severity should reflect the proximity/nearness to a crash ([Tarko, 2018](#)), but also the potential consequences of a crash. Following the vision zero philosophy, this is reflected in the proposed SMOs definition with the goal of “estimating the expected crash injury frequency.” Different SMOs are related in different ways to these two dimensions of the severity and will result in different interaction distributions and safety hierarchies.

Operationalization of Surrogate Measures of Safety

The current state-of-the-art regarding SMOs is described in the extensive literature review made in 2016 for the European project “In-depth Understanding of Accident Causation for Vulnerable Road Users” (InDeV) ([Laureshyn et al., 2016](#)).

Interaction Severity Indicators

The severity indicators for individual interactions, referred to as “measures of crash proximity,” were grouped in four categories by [Laureshyn et al. \(2016\)](#): the most common category is time-to-collision (TTC), followed by the postencroachment time (PET) and evasive-actions (deceleration).

The TTC Category

The TTC is the time remaining until a collision of two road users (or a road user with a stationary obstacle) assuming they continue traveling as initially planned. TTC is a continuous indicator that can be calculated at any time instant as long as there is a collision course.

To determine the existence of a collision course, that is, what travel was “initially planned,” is a challenge. In the case of an evasive action in the form of changed path, speed, or both, the initial intentions are not revealed and alternative motion prediction methods have to be used. The most simplistic and straightforward method is to assume that the speed and the heading remain constant. Clearly, this assumption does not hold in case of a turning maneuver which requires both changes in the motion direction and speed adjustments to negotiate the turn. Various modifications to this basic method have been suggested, for example, constant yaw or/and acceleration rates: yet, all these methods do not take into account the actual context, composed of the spatial context (road geometry) and the surrounding traffic, and may therefore predict very unrealistic trajectories and speed profiles.

The state of the art in context-aware motion prediction lies rather in learning the typical motion patterns based on observation of large amount of traffic performing the same maneuvers, with or without interactions with other road users (Saunier et al., 2007). The advantage of this method is that instead of poorly motivated kinematic assumptions, the prediction is made based on the actual motion being repeatedly observed, and can work well even in case of unusual geometry, for example in a construction zone. The method can be easily extended within a probabilistic framework, in which each road user has a variety of options for future motion. Combining these multiple future trajectories for a pair of road users yields at each instant a distribution of possible collision points, TTC values and their related probabilities (Gomaa Mohamed and Saunier, 2013). Two road users are on a collision course at a given instant if there is at least one possible future collision point. Such calculations, however, require large amounts of trajectories of normal traffic which requires an automated tracking tool.

At least two TTC values during an interaction deserve attention. Time-to-accident is the TTC at the instant the first evasive action starts, indicating the evolution of the situation from *unaware* to at least one of the road users realizing their collision course and attempting to mitigate it. The second value of interest is the minimal TTC, TTC_{min} , during the interaction, which represents the instant when road users are closest to a collision. The TTC concept inspired a wide range of modifications and new indicators. Some to mention are time to pedestrian crossing (time to zebra), inverted TTC ($1/TTC$), Time Exposed and Time Integrated TTC (describing the relation of a TTC curve to a pre-defined threshold), and T_2 (time for the latest road user to arrive to a predicted crossing point in case there is no collision course and TTC cannot be calculated) (Laureshyn, 2010; Laureshyn et al., 2016).

The PET Category

If the trajectories of two road users cross (overlap), the PET is the duration between the instant the first road user leaves the crossing zone and the instant the second road user reaches the crossing zone, that is, “PET indicates the extent to which they missed each other” (Laureshyn et al., 2016). There is therefore only one measurement at most for an interaction, but it may be measured in some situations where there is no collision course and therefore no TTC measured.

Like TTC, there have been several variations around PET. In a car-following situation, the PET is the same as the gap and similar to time headway. When using motion prediction as for TTC, PET can be also predicted, under the name of time advantage or predicted PET. For each pair of predicted trajectories at t_0 , they either cross or not: if they cross, let t_1 and t_2 be the arrival instants at the crossing zone of the first and second road users, respectively. There are two cases:

- the road users may be predicted to arrive at the same time ($t_2 = t_1$) and a TTC can be calculated as $t_1 - t_0$; OR
- there is a predicted PET calculated as $t_2 - t_1$.

The Evasive-Action Category

Deceleration is the most common evasive action taken by a driver to avoid a collision (Hydén, 1987). Several indicators based on deceleration have therefore been proposed. The first subcategory is for indicators based on observed road user deceleration. The magnitude of the deceleration at the beginning of the evasive action is called the (initial) deceleration rate. The maximum deceleration rate during an interaction has also been used, but these indicators suffer from the varying behaviours, and how the same deceleration may be normal for some users and extreme for others. The derivative of acceleration with respect to time, the jerk, reflects the suddenness of braking and has been shown to better discriminate severe interactions than deceleration.

The second subcategory is not directly observed: the minimal necessary deceleration for a driver to avoid a collision, assuming constant deceleration, was called the deceleration-to-safety time (DST), or the deceleration rate to avoid a crash (DRAC) in car-following situations. Similarly, in car-following situations, the safe stopping distance is the minimum distance required for the following driver to safely reduce speed and avoid a collision if the leader braked at the maximum deceleration and stopped. The proportion of stopping distance is the ratio of the current distance to the minimal acceptable stopping distance (Laureshyn et al., 2016).

An obvious shortcoming of this category is that indicators based on the deceleration or other evasive actions cannot be calculated if there is no such evasive action, if the road users are completely unaware of the situation or apply a different evasive action.

Other Indicators

There have been some attempts at creating indicators that can also reflect the outcome of crashes. The best known are related to Delta-V, a common notation in physics to denote an object's change of velocity because of a collision with another object. Delta-V is

correlated with the severity of real crashes. Based on motion prediction, an expected Delta-V can be calculated. It was extended to take into account evasive actions (braking) to reduce the impact forces. It may reflect both the nearness to a crash and the severity of the potential crash, and is suitable to represent vulnerability of road users, for example, pedestrians with motorized vehicles.

The TCTs developed in the 1970s and after rely to varying degrees on the *subjective* evaluation of the severity of interactions by observers in the field or from video recordings. These may be subjective evaluations of objective indicators such as distance, speed, and TTC. It was shown that observers can be trained to estimate speed and distance with sufficient accuracy to calculate time-related indicators like TTC (Hydén, 1987). Observers can also be trained to provide a holistic evaluation of the “dangerousness” of interactions by watching videos of severe interactions. Laureshyn et al. (2016) argue that these human subjective perceptions may come closer to the “true” severity compared to other objective indicators.

Data Collection Methods

The two most common ways to collect SMOs are *roadside* and *in-vehicle* (Tarko, 2018). As described above, TCTs were the earliest methods for road-side studies. Since the beginning, employing trained human observers to detect interactions and evaluate their severity has raised questions. This led to the search for more reliable and objective methods. Video analysis in particular has generated considerable interest, with a recent boom in the 2000s thanks to the lower costs of recording video and improved computer vision algorithms. Video analysis is rarely completely automated, with important initial configuration of the camera and scene configuration and tuning of algorithm parameters often done manually, and often requires users to annotate, correct or even completely manually track road users, detect relevant interactions and measure safety indicators (a list of existing software for video analysis and SMOs calculation is maintained at <https://www.ictct.net/surrogate-measures-software/>). Progress is ongoing in this area, as new sensors like LIDAR and methods from artificial intelligence may help completely automate the collection of SMOs. A long-term benefit of automated data collection is to provide researchers and analysts with large amounts of traffic data with various levels of safety to better understand the processes that lead to crashes.

In-vehicle studies are called naturalistic studies, most notably naturalistic driving studies. They typically focus on individual drivers/users, their behavior and interactions with the vehicle, the other users and the road. They rely on vehicle instrumentation for data collection. Such instrumentation is similar to available driver assistance systems, for example, forward collision warning based on measuring TTC with the leading vehicle. Severity indicators based on evasive actions, in particular deceleration and jerk, were developed to detect severe interactions in which drivers/users get involved, especially when limited data is available for the surrounding road users. Road-side and in-vehicle studies have complementary advantages and disadvantages: the former provides continuous temporal coverage for a limited part of the road network with little personal information about the road users, while the latter provides coverage for large part of the road network for more limited periods of time and possibly personal information about the users (if doing a survey).

An important question related to data collection methods is the duration of the study. Since interactions, like crashes, occur randomly, the study duration should be long enough to provide enough data so that safety can be estimated reliably. There is little research and a large variability in practice as reported in Laureshyn et al., (2016). Previous recommendations about study durations, for example, from TCTs, may not be relevant given the changes in traffic and the overall improvement in safety (decreasing frequency of crashes and severe interactions) since then.

How to Diagnose Safety

A good SMOs should have a clear relationship to safety, that is, the expected number of crashes/injuries. This is done in two main ways, either by counting the number of severe interactions as in most TCTs or by studying the distribution of some severity indicators and aggregating them. An important problem of the presented severity indicators is that many have been theoretically formulated but hardly followed by any empirical validation. The majority of the validation studies available have focused on TTC and PET, but no clear guidance can be given on which one to prefer as a measure of an interaction severity (Laureshyn et al., 2016). There has been little research on testing the various statistics that can be obtained from continuous severity indicators like TTC, aggregated spatially and temporally, while other researchers have tried different indicator combinations to better reflect the severity of each interaction.

In line with most TCTs, Tarko (2018) strongly argues that the sound basis for SMOs are severe interactions, given their etiological consistency with crashes. He provides a comprehensive summary of the mathematical models proposed for the relationships between the observed number of severe interactions $N_{interaction}$ and the expected number of crashes $N_{crashes}$, the simplest and earliest being a proportional relationship $N_{crashes} = \pi N_{interaction}$ developed in Hydén (1987), where the coefficient π was supposed to be constant. Yet, efforts to estimate such a model have been mixed as interactions and crashes are generally collected over different periods of time in different conditions, leading to π depending on these conditions (Tarko, 2018). More complex models have been proposed to estimate safety, notably through the counter-factual technique (causal inference) and extreme value theory or statistical exceedances.

Instead of counting severe interactions, the severity indicators may be directly used as dependent variables in statistical models (Zangenehpour et al., 2016). The distributions of the severity indicators by interaction can also be used, although it has not been established how interactions of different severity levels are related to safety. A statistical model can identify a statistical association between a treatment and an indicator like TTC_{min} , but it may not mean the same thing if the TTC_{min} are very small, indicating severe interactions, or much larger. A more holistic safety diagnosis may be derived from interpreting the distributions of severity indicators

including less severe interactions and finding how shifts in these distributions translate into safety. Early work showed for example very different severity distributions for a signalized and a nonsignalized intersection in Svensson (1998).

Perspectives

Despite the considerable rise in interest and progress over the last two decades, some challenges remain for the widespread use of SMOs. First and foremost is to establish validity of the proposed SMOs. This may seem like a moving target as a large proportion of crashes are not reported and safety has improved in many countries to the point that crashes are too rare at specific locations for validation between SMOs and crash statistics. Moreover, the properties of the road transportation system are changing very rapidly, too. The evolution of urban mobility systems toward streets for people (rather than cars) yields more walkers and cyclists interacting with motor-vehicle traffic, which in turn calls for new infrastructure designs, speed regimes, and general attitude and behavioral changes. On the other hand, technical progress in driver assistance technologies and the automation of driving tasks will probably have a dramatic impact on the traffic interplay, the relation between interactions and crashes, and safety.

At the same time, the same technological evolution provides more and more data from road-side and in-vehicle sensors. These will provide larger amounts of data and more complete data about interaction and crash processes. Analysis of such big data will strongly benefit from artificial intelligence methods, in particular machine learning techniques. Sensors in probe vehicles and from other users may be used for example to detect evasive actions like harsh decelerations and accelerations that enable cost-effective network-wide screening.

Another venue for SMOs is the use of traffic simulation. Crashes and interactions can be simulated, but the main issue, as for other measures, remains validity. Traffic simulations rely on complex driver models that are difficult to calibrate to real world conditions, while most do not involve the actual mechanisms leading to driver errors. Currently, most driver models represent perfect drivers, or robots, which do not generate any crashes in simulations. The correlations observed between the number of simulated interactions and observed severe interactions and crashes may be introduced by exposure.

Transportation modes with high safety profiles (air transport, railway) have recognized early the value of collecting data on out-of-normal incidents in conditions when very few severe crashes take place. It seems that the safety of road transport, at least in the Western world, is developing in the same direction. Waiting for several years to collect crash records is not a feasible option with the rapid changes in transport systems, leaving the scene to SMOs as the main tool for rapid feedback on safety. With a solid base developed over the decades and with the technical data collection tools reaching maturity, SMOs are about to get an important and possibly irreplaceable role in the toolbox of all road safety practitioners.

Introduction

Public surface transportation has become a theater of operations for terrorists. Passenger trains and stations offer terrorists easy access to crowds of people, often in confined environments, which enhances the effects of explosives or chemical substances and enables the terrorists to spread fear and alarm. While some terrorists aim primarily at disruption and others involve attempts to derail speeding trains, terrorists determined to kill in quantity and willing to kill indiscriminately find the dense throngs of commuters that fill stations and trains during rush hours the most lucrative targets. (Some supporters refer to individuals who target innocent civilians as “freedom fighters,” but their basic mission in carrying out attacks is to cause terror, so we use the term “terrorists.”)

In 2017 a bomb hidden in a briefcase exploded on a metro in Saint Petersburg, Russia, killing 14 people and injuring 64. Later that year, a would-be suicide bomber, angered by US military operations in the Middle East, detonated an improvised explosive device in a subway station in New York City. His crudely made bomb only partially detonated, injuring him and four other people. Another bomber, who had trained with terrorists in Syria, detonated a crude bomb at the Parsons Green Underground station in London, England. His device was also defective, but 30 people were injured in the explosion. (The statistics in this chapter derive from the Mineta Transportation Institute’s database of attacks on public surface transportation.)

In 2018 two persons were stabbed by a man at the Central Railway Station in Amsterdam, the Netherlands. That same year, another man injured one person and briefly held another hostage at the train station in Cologne, Germany, in what police believe may have been a foiled terrorist attack. In 2019 an assailant stabbed three persons at a train station in Manchester, England. In a separate 2019 incident, small bombs were mailed to London airports and the Waterloo train station.

These more recent, and mostly crude, attacks were typical of the kinds of primitive terrorist incidents seen in the late 2010s, and they contrast with the far deadlier attacks on rail passengers seen earlier: A 2004 commuter train bombing in Madrid killed 192 persons; the 2005 bombings of London Transport killed 52; the 2006 Mumbai commuter train bombing killed 209; the 2010 bombings in Moscow’s metro killed 40; and the 2016 bombing of a metro station in Brussels killed 20.

Recent Terrorist Campaigns

Terrorists do not descend to earth like extraterrestrials. They arise from political causes, as well as personal circumstances. Much of the recent terrorist activity directed against transportation targets reflects specific terrorist campaigns. What this means for those charged with security is that the level of threat varies greatly according to location.

History is filled with accounts of bandits holding up trains and insurgents derailing them. Bombs in trains or train stations were less common until the late 20th century. The Provisional Wing of the Irish Republican Army (IRA) was one of the first groups to initiate a bombing campaign targeting British rail passengers. For the first few years of “The Troubles,” the IRA concentrated its violence in Northern Ireland, but in 1973, in an effort to increase pressure on the British government, the group began carrying out bombings in London, initially focusing on government buildings but later targeting train and Tube stations, shopping centers, restaurants, and tourist sites.

Many of these attacks caused injuries, and some caused fatalities, but the IRA was cautious. It had far more capability than the generation of jihadist terrorists that operated in the United Kingdom decades later—the IRA knew how to make bombs. Its goal, however, was attention and political leverage, not high body counts. It worried about provoking backlashes that could repel its supporters and reduce its financial contributions from sympathizers abroad. Above all, it wanted to impose a high psychological and economic burden on the British public and its government as a price for remaining in Northern Ireland.

The IRA often provided authorities with warnings of where and when bombs were about to go off, claiming that it did so in order to give them time to evacuate the area and avoid casualties. While it is true that the group generally operated within self-imposed constraints, warnings were not always given; the information was not always precise and was sometimes misleading; some warnings

were deliberate hoaxes; and in some cases, the terrorists planted secondary devices aimed at killing police and soldiers sent to deal with the primary bomb. Providing “warnings” offered the group cover when people were killed by IRA bombs, allowing it to shift culpability to the authorities. The warnings were also a way to increase disruption.

In one incident, the IRA set off a bomb at London’s Paddington Station at 4:20 a.m. on February 18, 1991. The explosion did little damage and injured no one, but it established credibility for an IRA call warning that bombs would explode at all 11 of the mainline train stations in London at 7:45 a.m. There had been no IRA bombings of London stations since 1976, and the authorities were reportedly slow to react. They tried to check for devices before halting all incoming trains and entirely evacuating every station, which would have put thousands of people into the streets. As a result, passengers were still present on a crowded platform when a bomb hidden in a trash can went off in Victoria Station at 7:40, 5 minutes before the detonation time given in the warning. The explosion killed one person and injured 38. Fearing further casualties, authorities shut down all of the other train stations for the first time in history.

The deadly cat-and-mouse game continued. In February 1992, the IRA gave just a 10-minute warning before a bomb exploded at the London Bridge Station. There had been enough real bombs to give the warnings credibility. The warnings were calculated to force the authorities to evacuate large facilities quickly, creating potential panics, giving them just enough time to respond but not enough time to search. To avoid catastrophic casualties, the IRA usually used small, although still lethal, devices, and the attacks escalated over time. The IRA campaign against British transport is described in detail in [Jenkins and Gersten \(2001\)](#).

The Basque separatist group Euskadi Ta Askatasuna (ETA) was a contemporary of the IRA. Beginning in the late 1960s, it carried out a campaign of assassinations, armed assaults, and bombings directed against Spanish government officials, Spain’s security forces, and civilian targets, which included rail systems. ETA claimed responsibility for or was directly linked to 25 attacks on transportation targets; another 77 unclaimed attacks were also attributed to its terrorist campaign. ETA was even more cautious than the IRA about civilian casualties. Its attacks on transportation targets were intended to demonstrate capabilities, cause fear and disruption, and discourage tourism as part of its campaign of economic warfare. Most of its attacks targeted empty trains and stations. When ETA planted bombs where civilian bystanders were likely to be killed, it—like the IRA—provided warnings. Only two of its many attacks on rail targets resulted in fatalities: Four people were killed by bombs detonated in the Atocha and Chamartín train stations in Madrid on July 29, 1979. Five other attacks resulted in injuries.

However, as is the case in many terrorist campaigns, there was pressure to escalate the violence. In December 2003, Spanish police thwarted an ETA plot to detonate two suitcases containing bombs with more than 50 kilos of explosives on a train in Madrid’s Chamartín train station on Christmas Eve. The arrest and interrogation of the individual attempting to plant one bomb alerted police to the second bomb, which was already on its way to Madrid. Authorities halted the Madrid-bound train, evacuated its passengers, and defused the device. The terrorists had also planned to detonate two smaller devices on the rail lines in Aragon. On February 29, 2004, police arrested two ETA members driving vans carrying 536 kilos of explosives on their way to Madrid. The terrorists planned to detonate a massive vehicle bomb there on the day of the national elections, scheduled for March 14.

It is understandable, therefore, that ETA would be at the top of the list of suspects when bombs went off on commuter trains arriving at Madrid’s Atocha rail station on March 11, 2004. However, police quickly realized that the design of the devices and the explosives used were different from devices fabricated by ETA. This, plus other evidence that was gathered, convinced police that the bombs were the work of jihadists, not Basque separatists. The police were therefore surprised when the Spanish Minister of Interior announced that ETA was responsible, a claim that Spanish political leaders persisted in making despite overwhelming evidence to the contrary. This infuriated crowds who considered the government’s claim as an attempt to cover up what people saw as a terrorist attack in retaliation for Spain joining the United States in the invasion of Iraq. A detailed analysis of the March 11 bombing by [Reinares \(2017\)](#) makes the point that both sides were wrong: ETA was not responsible for the attack, despite continuing conspiracy theories; and the decision by the jihadists to carry out a major terrorist attack in Spain was made in December 2001, the jihadist network in Spain that carried out the attack assembled in March 2002, and al Qaeda’s senior leadership approved the plan in October 2003, all long before Spain joined the American-led coalition to invade Iraq.

Transportation targets were not a feature in the terrorist campaigns of Germany’s Red Army Faction or Italy’s Red Brigades terrorists in the 1970s and 1980s. Neo-fascists in Italy, however, bombed an express train in Italy in 1974, killing 12 people and injuring 48, and they bombed the Bologna Central railway station in 1980, killing 80 people and injuring more than 200. The Sicilian Mafia was believed responsible for the bombing of a passenger train in 1984 that killed 16 and injured 256.

Escalating Violence

Terrorist attacks on transit targets in the 1970s and 1980s were seldom intended to cause mass casualties; separatists and ideologically motivated groups had constituencies, which they did not want to alienate. (Italy’s neo-fascists and Mafia were exceptions.) However, as terrorists in general escalated their violence in the 1980s and 1990s, attacks on transportation systems became deadlier. Transportation venues became killing fields.

On March 20, 1995, members of Aum Shinrikyo, an apocalyptic Japanese cult, released plastic bags filled with sarin, a lethal nerve agent, on five Tokyo subway trains as they reached the central part of the city, where government buildings were concentrated (see [Jenkins and Gersten, 2001](#)). Because the quality of the sarin manufactured by the group was poor and the method of dispersal was primitive, only 12 persons died in the attack, although more than 1000 people were directly exposed to the fumes, and more than 5500 were treated for a variety of medical conditions related to the attack. Had the sarin been more potent and the dispersal more effective, the number of deaths would have been much higher.

Weeks later, Aum Shinrikyo members still at large attempted another attack on Tokyo's subway system, this time using hydrogen cyanide. The dispersal scheme did not work as planned, although four people were injured. With these incidents, chemical weapons had become part of the threat matrix. However, old-fashioned bombings and derailments caused by sabotaged rails continued to account for the highest-casualty attacks.

In July 1995, a small group of Algerian extremists, angered by France's support of the Algerian government in its war against Islamists, detonated an explosive device aboard a French commuter train at the St. Michel station in Paris. Seven persons were killed and more than 80 were injured in the blast. This was the first of a series of attacks, several of them directed against transportation targets, that continued until mid-October. In August, the terrorists unsuccessfully attempted to derail a high-speed train between Lyon and Paris. In October, a bomb exploded on a commuter train in Paris, injuring 30. The campaign, which is described in [Jenkins et al. \(2010a, 2010b\)](#), appeared to end when police arrested most of the members of the terrorist network in November 1995, but another bomb detonated on a commuter train in Paris in December 1996, killing four persons and injuring more than 90.

Police uncovered several jihadist plots against French rail targets in the early 2000s, and a 2015 attempt to gun down passengers on the high-speed train between Amsterdam and Paris was foiled by passengers. Although a group of French and Belgian veterans of the Islamic State carried out devastating terrorist attacks in Paris in November 2015, transportation targets did not figure in their planning. However, the same network carried out a bombing on the Brussels metro in 2016, killing 20 people (see [Jenkins et al., 2016](#)).

Between 2003 and 2017, Chechen rebels and Islamists carried on a deadly bombing campaign targeting passenger trains and stations and urban metros in Moscow and other cities in Russia, killing more than 240 people and wounding many hundreds more (see [Jenkins and Butterworth, 2014a](#)). In 2017 Islamic State supporters from Tajikistan attempted to sabotage a high-speed train, causing it to derail in the path of another train traveling in the opposite direction. The trains did not crash and there were no casualties, but the coaches sustained extensive damage.

India has experienced more attacks on surface transportation than any other country and has suffered some of the deadliest incidents. Terrorist attacks on commuter and intercity passenger trains in India became increasingly common in the first years of the 21st century. In 2002 sabotage caused the derailment of a high-speed passenger train crossing a bridge, resulting in between 130 and 200 fatalities; and 209 people died in the 2006 bombing of a Mumbai commuter train. In 2007 bombs in the coaches of a passenger train killed 70. Another 148 persons died in the derailment of another passenger train in 2010, although the conclusion that it was sabotaged has been disputed.

The deadliest incident in a subway occurred in Daegu, South Korea, where a mentally unstable individual deliberately started a fire on the train, ultimately killing 198 persons. (The incident with the most total fatalities took place during Angola's civil war in 2001, when rebels derailed a passenger train and then shot fleeing survivors; about 100 people were killed in the initial attack and more than 150 were chased and shot down—in all, 256 people are believed to have died.)

In comparison to the high volume of attacks in South Asia and Russia, Canada and the United States have suffered few attacks. Between 1970 and September 2019, 12 attacks occurred in the United States, and four occurred in Canada. Only three of these—two of them by deranged individuals—resulted in fatalities.

Attacks by Islamist fanatics have been the source of greatest concern in the first decades of the 21st century. The deadliest attacks—most notably the 9/11 attacks on the United States—and many of the foiled plots during the first decade of the 21st century were part of an ongoing global campaign of terrorism directed against a variety of targets in countries branded by jihadists as enemies. This terrorist campaign was inspired by continuing exhortations from al Qaeda leader Osama bin Laden and other al Qaeda communicators, and it was waged by individuals who subscribed to al Qaeda's ideology, some of whom had trained in its training camps or had learned from information posted on various jihadist websites. This is not to say that the campaign was centrally directed.

Jihadists were responsible for the most-lethal surface-transit-system bombings, including the 2004 Madrid train bombing, the 2005 London Tube bombings, the 2006 Mumbai train bombing, and the train and metro bombings in Russia. An analysis of jihadist targeting preferences in Europe between 1996 and 2016 ([Hemmingby, 2017](#)) showed that transportation (aviation and surface) was the most frequent intended target in jihadist plots, ahead of public areas in general.

Jihadist attacks typically aim at death, not disruption. In Europe and North America, jihadists have been responsible for only 11 of the attacks on surface transportation, but approximately half of the total casualties. The jihadists have also made extensive use of suicide bombings.

The term "jihadist" gets slippery outside of Western countries. The Chechen insurgency in Russia started out as an independence movement, but over time it acquired a more radical jihadist ideology. Whether China's Uighur combatants, who have carried out deadly terrorist attacks on transportation targets, should be counted as separatists or jihadists depends on the perspective of the viewer. Their quarrel is largely local—they oppose rule by Han Chinese—although they have reportedly received support from al Qaeda, and some of their leaders describe their struggle as a religious jihad (see [Jenkins and Butterworth, 2014b](#)). And while some of the attacks on India's railways are inspired by jihadist ideology, Indian authorities believe there is considerable evidence that the jihadists are proxies of Pakistan's intelligence service in a continuing covert war between the two countries.

Police have thwarted numerous jihadist plots, in addition to the foiled attacks on transportation targets. British authorities uncovered plots to disperse poison gas and ricin on London trains in 2002 and 2003. Just two weeks after the July 7, 2005, bombings on London transport, a second jihadist group tried to replicate the attack, but their devices failed. In November 2005, Australian authorities uncovered a plot to carry out attacks in Sydney and Melbourne; targets included Melbourne's landmark Flinders Street Rail Station. In 2006 homegrown terrorists inspired by jihadist ideology planned to detonate two bombs hidden in suitcases on German commuter trains, but the devices failed to detonate. That same year, Moroccan police uncovered a jihadist plot to bomb Milan's metro. In 2008 police in Spain uncovered a jihadist plot to carry out bombings on Barcelona's metro.

Several jihadist plots have targeted subways and commuter trains in the United States. In 2003 jihadists planned to release cyanide gas in New York's subway system but reportedly were diverted to another project. Authorities thwarted a plot by homegrown jihadists to bomb a subway station in midtown Manhattan in 2004. In 2006 Lebanese authorities discovered another jihadist plot to bomb trains in the tunnel under the Hudson River. An American jihadist who traveled to Pakistan offered his experience as a former employee of the Long Island Railroad to help al Qaeda plan and execute a terrorist attack on that system. He was arrested by Pakistani authorities and returned to the United States in 2008. The following year, acting on a tip from British authorities, FBI agents uncovered the existence of a group of jihadists planning to carry out suicide bombings on New York's subways. Another individual was arrested the following year in an undercover operation. He intended to carry out a bombing on the Washington metro. The discovery of notes in Osama bin Laden's compound indicated that he also was contemplating attacking trains in the United States on the tenth anniversary of September 11, 2001.

The jihadist campaign reached a high point in the mid-2000s, with three major terrorist attacks on trains in Madrid, London, and Mumbai, and seven foiled plots between 2004 and 2006, after which the campaign declined.

The continuing revelation of jihadist plots underscores the reality of the threat—there is always someone out there planning to do something. And, given ongoing conflicts in the Middle East, it must be presumed that the threat will continue. Historical experience shows that if they are not thwarted, these attacks can have terrible consequences—fatalities in the scores or hundreds, potentially more if chemical weapons are used effectively.

There have been several plots involving crudely refined ricin possibly being spread in train stations or coaches, none of which would have caused mass casualties. And there is at least one case of deliberate radioactive contamination. In 1974 an individual with a history of mental illness spread nonlethal quantities of radioactive Iodine-131 on train coaches in Austria. The perpetrator intended his action, which received widespread publicity, as a protest against Austria's treatment of the mentally disturbed (DeLeon et al., 1978).

Nevertheless, terrorist attacks are statistically rare, and the overall threat to life is only a small fraction of the total casualties resulting from ordinary transportation accidents—trains colliding with vehicles at grade crossings, people walking on tracks or in tunnels, suicides by train.

Trends in Tactics and Targeting

Terrorist attacks on surface transportation targets have increased over the long run. Between 1970 and 1979, terrorists carried out a total of 23 surface transportation attacks that caused fatalities. (Only incidents with fatalities are included in this analysis to mitigate increases that may be due solely to better reporting.) The number grew to 44 attacks with fatalities in the 1980s, 271 in the 1990s, 446 in the decade between 2000 and 2009, and 814 in the decade between 2010 and (October 15) 2019. These numbers include attacks on both bus and passenger rail targets.

Many of the attacks on surface transportation involved few or no fatalities and did not make headline news, but 11 of them since 9/11 resulted in 50 or more deaths, and three of the attacks killed approximately 200 people each. The total number of fatalities in these 14 attacks would translate into the casualties from anywhere between 6 and 18 commercial airline crashes. The regulatory evaluation method used in 2001 to derive this estimate for airline crashes was based on an average of 78 passengers for a loaded Boeing 737. At the high end, one can instead look at the 1988 PanAm 103 and 2015 Russian Metrojet sabotage incidents to calculate an average of more than 200 fatalities per incident. The average number of fatalities in the four airline crashes caused by terrorist sabotage since 9/11 is 106.5, which would give a rough equivalent of 13 crashes. One can imagine the fear and furor that would have resulted if 13 commercial airliners had been brought down by terrorists after 9/11.

The total number of fatalities caused by attacks on surface transportation also increased, although both the number of incidents and the number of fatalities declined sharply after 2015. Lethality is more complicated. The Mineta Transportation Institute's database of attacks on surface transportation tracks lethality, measured as fatalities per attack (FPA). The annual average FPA (total fatalities divided by the total number of attacks) charted over the years shows whether attacks in general are becoming bloodier.

The record shows that overall lethality—the average number of FPA—has declined slightly over the years. This may reflect the growing volume of low-level attacks, which lowers the average lethality. For example, two attacks that caused 150 and 85 deaths occurred in 1980, when there were far fewer incidents overall, and thus drove up the average FPA for those years. This sharp peak, in turn, distorts the linear trend line. Excluding these two incidents tilts the trend line slightly upward. We also cannot dismiss the possibility that some portion of the increased volume of incidents recorded in recent years may be due simply to better reporting as more local news accounts become available via the Internet.

Bombings account for most of the attacks on surface transportation and most of the casualties. They are also the most lethal form of attack. Improvised explosive devices account for 51% of the total attacks. Explosives, including improvised explosive devices, grenades, mines, and dynamite, account for almost 60% of all attacks (see Jenkins and Butterworth, 2010). Shootings and armed assaults—incidents involving only firearms, including hijackings—account for 15%. Incendiary devices and other forms of arson account for nearly 13% of all attacks, and mechanical means of sabotage (mostly of rails) account for about 3%.

Not all attacks on rails themselves are intended to derail trains. In many cases, the saboteurs—anarchists, environmental extremists, opponents of nuclear power and weapons—seek only to cause disruption, thereby bringing attention to their cause and imposing an economic cost and inconvenience on society.

Recently, there has been an increase in more-primitive terrorist tactics—stabblings and vehicle-ramming attacks (see [Jenkins and Butterworth 2018a, 2018b; Jenkins et al., 2019](#)). There are also incidents in which people are pushed off platforms into oncoming trains. The trend reflects changes in how terrorists are recruited. In the past, terrorists usually joined small underground groups, which carefully vetted them to prevent infiltrators or individuals judged to be unreliable. In contrast, much of today's recruiting is done by exhortation. Jihadist groups, in particular, have exploited the Internet and social media to inspire followers abroad to carry out attacks wherever they are, using whatever means they have available. Often operating alone, the recruited individuals have limited resources and skills. Guns, where they are easily available, may be used. Knives and vehicles are readily accessible almost everywhere.

Remote recruiting emphasizes the violence of attacks as much as the cause, and it appeals to a broader audience of potential actors that includes not only fanatics, but individuals with histories of aggression and violence, as well as mentally disturbed persons. Intense media coverage adds to the attraction. The result is random attacks by individuals untethered to organizations.

It is low-yield ore—there are handfuls, not hundreds, of attacks in any country. The risk to the individual traveler is infinitesimal. Nonetheless, the very randomness of the violence creates an impression that no location is safe. The psychological effects of terrorism, which is above all about creating fear and alarm, create anxiety and psychological disorders that can last years. Media coverage creates a vast audience of vicarious victims. At the societal level, continuing fear fuels suspicion, generates demand for extreme measures, and exacerbates social divisions and other tensions.

Security Issues

Security for public surface transportation must be realistic. Protecting public places that by their very nature require easy access is difficult and costly. Prevention of all attacks is virtually impossible. (The challenges of protecting surface transportation against terrorist attacks are described in detail in [Jenkins, 2017](#); see also [Taylor et al., 2005](#).)

It can be argued that the extraordinary security measures deployed over the years at commercial airports have significantly reduced the number of airline hijacking and sabotage incidents, which is true, although other factors have also contributed to the decline. However, an aviation security model will not work for surface transportation. The number of passengers using urban rail in the United States daily is more than four times the number boarding planes.

The architecture of the two systems is also completely different. Airports are designed to funnel passengers onto airplanes. Transit stations are open systems designed to let as many people on and off trains as quickly as possible. Given the limits of current and even near-term technology, to replicate aviation security for surface transportation would require several hundred thousand screeners, add unacceptable delays to daily commutes, and impose costs that would likely destroy public transportation as it currently exists. Screening of 100% of passengers can be imposed only where governments exercise great social control and there are no alternate ways to travel. It is unlikely to work elsewhere.

The check-in and baggage pickup areas at airport terminals, which are outside of the checkpoints for passengers boarding planes, have also been venues for terrorist attacks. Security officials face the same problems there as do those charged with the security of transportation—crowds of people in public areas. Some airports have established outer security perimeters to surveil and screen passengers as they arrive at the airport or enter the terminal. This is a completely separate function from passenger screening to prevent weapons and explosives from being smuggled on airlines.

There is another important conceptual difference between protecting airplanes and protecting transit systems. Airline security is front-loaded, that is, it aims at deterrence and prevention. In contrast, surface transportation encompasses a broader spectrum of countermeasures, including deterrence, detection, prevention, mitigation of casualties through the design of coaches and stations, and reducing fatalities by prompt detection and rapid intervention when events do occur and by facilitating evacuation and rescue. In the case of armed assaults, rapid intervention can prevent further killing. The multitude of entry points and passenger volumes limit what can be done at the front end, but there are still opportunities to save lives, even during a terrorist event. Detection can be improved, and casualties can be further mitigated by station and coach design.

Aviation security is highly regulated. Rules must be standardized to ensure that passengers go through the same security procedures no matter where they enter the system. The same strict regulatory approach would not work for surface transportation, nor is it necessary. A train or bus passenger does not enter an international or even a national system. Local systems vary greatly in size, configuration, passenger volumes, and other attributes. Security may be provided by local police, specialized transport police, proprietary police departments, or private security. Instead of standardized rules, operators follow a best-practices approach.

Governments and other sources provide information about terrorist events and lessons learned. Individual transportation operators decide what is appropriate for their local threat situation and circumstances. Government may provide additional support in the form of intelligence about possible threats, research, and security-technology assessments and may further provide material assistance to assist operators in the development and deployment of new security measures.

Rail operators and transit systems have increased the presence of security personnel. They have added cameras to improve surveillance, assist in rapid diagnosis if an event occurs, and deter terrorists who want to avoid capture. Smart camera systems alert monitors to anomalies, for example, objects that do not move when they should or movement where there should be none, and can assist in tracking the past or current movements of persons arousing suspicion. Some systems have installed platform-edge doors.

Explosives-sniffing dogs are increasingly being used to search for bombs and detect vapor trails left by explosives. Remote explosives-detection technologies are being deployed on an experimental basis, but there is no near-term technological solution.

Some transportation systems have implemented random passenger screening, which introduces uncertainty for attackers. It is difficult to determine how much deterrent value such screening efforts may have, but they establish protocols, allow for training, and thereby provide a foundation for an orderly surge in security, should intelligence provide some warning of an increased threat level, or in the immediate aftermath of an event to discourage further planned or copycat attacks. These measures are also flexible and can easily be scaled back when an immediate threat is seen to diminish.

Most security measures enhance security, but local governments and transit operators, strapped for cash, can do only so much. They are often dealing with ordinary crime, aggressive behavior, homeless populations, and other challenges that upset passengers and discourage ridership. Whatever security measures are put into place must be sufficient to handle the huge volumes of passengers, must not trample civil liberties, must be economically sustainable, and must offer a net security benefit. Implementing such measures will require intelligence and imagination.

A realistic appraisal of the threat posed by terrorists must take into account the minuscule risk that they pose to passengers and the broader society. The number of persons killed by terrorists attacking rail passengers is a tiny fraction of the number killed in passenger railway accidents, mainly collisions with vehicles at level rail crossings or people being hit by trains while walking on the tracks. In 2019 The European Statistical System (Eurostat) found that in Europe, the number of people who die in suicides by train is greater than the number killed in accidents. To be sure, terrorist attacks attract more headlines and generate fear, and this causes people to exaggerate the threat.

An often overlooked cost of terrorism is the panoply of psychological effects—the terror—that can be immediately observable but may also persist over long periods of time and have a corrosive effect on society in general (see [Greenberg et al., 2009](#); [Sheppard, 2009](#)). Although the level of apprehension may seem to be a broader societal issue beyond the responsibility of transportation system operators, it may be directly affected by how effectively and efficiently government and transportation operators handle terrorist crises.

Often, this is a matter of communications—providing accurate information about what is going on, rapidly setting up centers where concerned people can obtain information about relatives who may be victims, arranging and informing the public about alternate means of transportation, rapidly countering rumors, and other messaging to reflect competence. Security measures rapidly put in place to reassure nervous passengers and deter copycats or malicious pranksters can acknowledge and respond to reports of suspicious objects or people from passengers who are understandably frightened and therefore hyperalert.

Employee and passenger awareness counts. Just as airline passengers have become the last line of defense against terrorists on airplanes, rail passengers can become the first line of defense in ensuring their own security. Daily riders know the environment intimately and are able to identify suspicious objects or behavior.

During the IRA bombing campaign, British authorities depended on alert passengers, already sensitized by IRA bombings, to report suspicious objects within minutes of the objects' being placed. Reports were followed up with visual diagnosis through cameras and personnel on scene. Bomb squads were summoned only when necessary, thereby minimizing disruption. This made London's Tube and trains a hostile environment for terrorist operatives. One can see the results over time, as the terrorists gradually edged away from their preferred targets in crowded central London to more-remote venues.

The Mineta Transportation Institute has examined the issue of citizen awareness in detail (see [Jenkins and Butterworth 2018a, 2018b](#)). Researchers there found that since 1970, on-site police, security personnel, transportation employees, and passengers have prevented 10.6% of all attacks on surface transportation by reporting suspicious objects. The overall detection rate was 14.2% in the higher-income countries—particularly in Europe and North America—where, in response to terrorism, "See Something, Say Something" campaigns have been emphasized. For trains and subways, the figure is 14.8%.

Current "See Something, Say Something" campaigns need to be further evaluated to see if the message is getting through and to determine how to better engage the public. Communications by members have to be facilitated—an easier task in the age of widespread mobile phones. Procedures have to be established to ensure rapid diagnosis and response. Callers need to be acknowledged for their efforts, even when an effort turns out to be a false alarm. Disruptions must be minimized.

Finally, it should be noted that police intelligence operations account for a majority of the failures of terrorist plots. Intelligence collection is a national effort that extends far beyond the security force charged with protecting a particular transportation system. However, transit police forces have developed creative ways to enlist staff, riders, vendors, and nearby merchants as additional eyes and ears. In today's terrorism, the tip that leads to uncovering a terrorist plot may just as easily come from a local source as from a foreign intercept.

Introduction

Sweden has a long experience of a holistic, systematic, and strategical road safety work, introduced in the late 1960s in connection to and after the switch to right-hand driving in 1967. One important step was the establishment of a special government agency for road safety, the Swedish Traffic Safety Agency, in 1968. The number of people killed on the roads dropped from 16.7 killed per 100,000 inhabitants in 1966 to 9.1 killed per 100,000 inhabitants in 1982—a decrease of more than 40%. During the 1980s, the positive trend was broken and the road injury figures and the traffic growth began to follow each other like they had in the 1950s and early 1960s: the more car traffic, the more people were killed on the roads. In 1989, Sweden had 10.6 fatalities per 100,000 inhabitants and was, once again, approaching four-figure numbers of road deaths. A sense of lost control was spreading in society and this, together with political pressure, led to something more radically done about the problem. This eventually (in 1993) led to the closure of the Swedish Road Safety Agency and to an enhanced role for the Swedish Road Administration.

Parallel with this process to change the institutional prerequisites for the national road safety work, Sweden faced a severe economic recession in the first half of the 1990s. During the period 1990–93, the Swedish GDP dropped by almost 5% and the unemployment rate increased dramatically. From a road safety point of view, at least in the short run, we know that economic recessions might be good for safety and this was the case for Sweden in the 1990s. The number of fatalities dropped by more than 40% between 1989 and 1996 from 904 to 508.

However, with the recent negative trend in deaths and injuries on the roads in the 1980s freshly in mind, together with the knowledge that the recession gradually would change into a more normal pattern of economic development, road safety experts in Sweden shared a common insight that something different was needed. Strategies adopted in the late 1960s and business as usual was not a long-term sustainable strategy.

In 1994, a development work was established. This was led by Claes Tingvall, a former Road Safety Director of the Swedish Road Administration, and documented in a memorandum entitled “Vision Zero—An Idea for a Road Transport System Without Health Losses.” Vision Zero quickly attracted political interest, and the Minister of Transport and Communications at the time, Ms. Ines Uusmann, initiated a broad public policy process that culminated in October 1997 with the Swedish Parliament adoption of Vision Zero as a new national public road safety policy ([Swedish Government and Committee on Transport and Communications, 1997](#)).

It is now more than 20 years ago that the Swedish parliament adopted Vision Zero and this approach to safety has since then been spreading around the world and to other sectors of society. In this paper, the Swedish Vision Zero and its basic characteristics, its implementation, and results are described and explored.

Vision Zero as a Public Road Safety Policy Innovation

The Swedish Vision Zero is described and analyzed in many different studies and documented in scientific literature ([Tingvall et al., 2000](#); [Johansson, 2009](#); [Belin and Tillgren, 2012](#), [Kristianssen, 2018](#)), governmental reports, conference proceedings, and presentations. Vision Zero is a long-term goal to eliminate fatalities and serious injuries and it is based on an ethical imperative, which states that society can never accept that people are killed, or seriously injured when they travel in our road transport system. However, Vision Zero is more than this ethical imperative. It is a comprehensive theory, a belief system of different ideas, which connects to each other in a logical way. Broadly speaking, it contains ideas about the road safety problems and its causes, what future conditions the society should aim for to achieve “safety,” and the appropriate ways to reach these short- and long-term conditions. In order to explore the innovative characteristics of Vision Zero, it could be useful to compare it with a traditional approach to road safety ([Belin and Tillgren, 2012](#)). As follows, the ways that society defines its problems are paramount for what both people and organizations believe are appropriate strategies and goals. Let us start with looking at the predominant traditional approach and then move on to Vision Zero.

Population/ system perspective	People are victims in a complex technological system	People in general are influenced by wrong social norms
	Some individuals do not have the psychological and biological traits which are needed	We have subgroups of people who do not comply with social norms
Individual risk groups	Human traits “Error”	Human willingness “Violation”

Figure 1 Accident causations theories.

A Traditional Approach to Road Safety

The traditional road safety work focuses mainly on the problem with accidents or, as some researchers and policy-makers prefer to say, crashes. The definition of road safety problems is, to a significant extent, based on in-depth studies, which draw the conclusion that roughly 90% of all road traffic accidents can be explained by human factors, solely or in relation to its environment (Evans, 2004). Which type of human factors, human errors, or human violations that causes most safety problem is, however, an area of constant debate among scholars through the history. System-oriented human factor experts tend to focus on human errors, while social norms individual human behavior experts tend to focus on individual traits and subgroups (risk groups) (Fig. 1). In general, the individual perspective—and human error explanations—dominates among road safety experts around the world.

The statement that 90% of all accidents (crashes) are due to human factors is a powerful tool to direct interventions and to support society in their efforts to distribute responsibility for safety. The principal challenge, according to a traditional approach, is to prevent conscious and subconscious faulty individual human actions and its ultimate aim is to create a perfect human being, who always does the right thing, or to prevent faulty humans to get access to the system. The main strategy in order to achieve this has been to regulate individual road users' access to the system and its individual road user behavior (e.g., capability and willingness to comply) (Friedland et al., 1990). According to a traditional point of view, the individual road users are responsible for controlling and managing their own risks that may occur when traveling on the road transport system; and the individual road users are therefore ultimately responsible for their own and other's safety. If something goes wrong in the road transport system and an accident occurs, it is, in almost all cases, possible to find an individual to blame. The Vienna Convention of 1949 and the Vienna Convention of 1968 are excellent examples of how this universal principal of responsibility is formalized, and this is also reflected in the insurance systems surrounding road transport. Traditional road safety work is therefore largely focused on the so-called three E strategies—engineering, enforcement (regulation), and education—directed toward individual road users in order to modify their behavior with the intention of reducing the number and severity of accidents.

The ultimate goal, with a traditional approach to road safety, is to gradually reduce risks within the system but there is a limit for how far we can go. According to this traditional approach, it is unrealistic to eliminate the human factor and reduce the number of accidents to zero. People are willing to take risks and neither individuals nor society wants absolute safety and the perception is that it would be too costly to eliminate all accidents. Society therefore has to accept losses of human life and long-term health. The perception is that fatalities and serious injuries in the road transport system is a price that we have to pay for our mobility and our individual freedom. As a result of this, the long-term goal is to reach an optimal level of fatalities and serious injuries and strike a balance between costs and benefits to achieve this (Elvik, 2009).

The Vision Zero Approach

Vision Zero, as a road safety approach, does not deny the fact that human factors play a crucial role in the occurrence of accidents, but instead of defining this as the basic problem which needs to be solved, Vision Zero is based on the idea that human beings always will make conscious and subconscious mistakes. There is no perfect human (or machines for that part), there never will be, and we have to accept that accidents will occur. Instead of focusing on prevention of accidents, per se, Vision Zero rather focuses on severe injuries as the basic problem that needs to be solved. According to Vision Zero, the principal cause as to why people die and are seriously injured is that the energy to which people are exposed in a traffic accident is too excessive in relation to the energy that humans can withstand. This is not a new idea. These ideas are to a large degree based on the thoughts that Dr. William Haddon developed and elaborated upon already in the middle of the 1960s (Haddon, 1968, 1970). However, Haddon's utmost important contribution to

Figure 2 The Reason's cheese model applied on road traffic safety.

the road safety community has not been frequently adapted in the design of our road transport system except for in parts of the car design (e.g., crashworthiness) and individual protection equipment (e.g., helmets, seat belts, child restraint systems, etc.).

The basic strategy that underpins Vision Zero is therefore injury prevention rather than accident control. Vision Zero is a holistic policy that aims to create a safe system in the long run. The components, that is, roads, vehicles, and traffic environment and behavior, need to be integrated into a system that delivers safe mobility for all road users. All these aspects need to be designed as barriers and thereby control potential harmful energy to reach individual road users. We therefore need to add a prevention model to the famous injury causation model: precrash, crash, and postcrash. Based on Reason's "cheese model" (Reason, 1997), the road transport system and its different individual components could therefore be arranged into different protection layers (Fig. 2). According to this model, trauma care is the last protective layer just after individual behavior. The road environment is the first and most general and comprehensive protection layer that, to a large degree, defines what kind of accident types that could happen in what energy level. For example, if the roads were designed to eliminate head-on collisions (e.g., motorways, 2 + 1 roads) then the severity of factors, such as drink and driving, fatigue, distraction, among others, would also be eliminated. In a Vision Zero approach, the design of the road environment, both rural and urban, is the most important protection layer. Vehicles is the next protection layer and both the factors, how the vehicle can be used and its protection characteristics, play an important role. For example, cars, both top and dynamic speed performance, are important to support drivers to choose an appropriate speed. Nowadays, there are technologies such as intelligent speed adaptation systems that prevent drivers from speeding. Based on the design of the environment and the vehicle safety performance, safe speed limits could be set. If the road environment and the vehicles were well designed, from a safety perspective, a higher speed limit and mobility could be accepted. Poor safety standards will therefore instantly influence the mobility in the road system. In a Vision Zero approach the rural and the urban road environment, vehicle safety performance, and speed limits are therefore the most important protection layers and these need to be designed and operated according to safe system principles.

The road transport system is a complex system and there are several stakeholders at different levels in our society that influence the design and the operation of the system. Instead of putting the ultimate responsibility for safety on us as individual road users, Vision Zero puts the final responsibility for safety on those stakeholders who design and operate the system. The responsibility for safety is thus split between the road users and the system designers (i.e., infrastructure builders and administrators, the vehicle industry, the haulage sector, taxi companies, and all the organizations that use the road transport system professionally), on the basis of the principles that:

- the system designers have ultimate responsibility for the design, upkeep, and use of the road transport system and are thus responsible for the safety level of the entire system;
- as before, the road users are still responsible for showing consideration, judgment, and responsibility in traffic and for following the traffic regulations; and
- if the road users do not take their share of the responsibility (e.g., due to a lack of knowledge or competence) and personal injuries or other risky situations occur, the system designers must take further measures to prevent people from being killed or seriously injured.

In Vision Zero, the responsibility for safety is a chain that both begins and ends with the system designers.

Vision Zero is also based on the idea that individuals and society want and demand safety. The fact that people sometimes act as though they do not need safety rather seems to do with inability, ignorance, and a lack of social support than a lack of will. Not even suicide, in most cases, is a deliberate act based on the willingness to die. It is rather a desperate expression that the life is too difficult to tolerate and there are no other options to be seen. The long-term objective of Vision Zero is to create safe (e.g., no fatalities and no

serious injuries) mobility. Vision Zero as a public policy will therefore dramatically change our perception on mobility versus safety in our road transport system. Mobility becomes a function of safety rather than the other way around. This is nothing new; it is the way things work in other parts of our society and other transport systems. For example, if we discover safety problems in our aviation system that might threaten people's lives we stop the air traffic until we have fixed the problem. Luckily, we do not have to stop the road traffic in order to achieve safe mobility, since it, in most cases, is enough to reduce speeds.

Vision Zero—To Make Things Happen

Although we still need more road safety research, over the years a comprehensive knowledge base has been developed about traffic safety and what factors in the road transport system (e.g., road, vehicle, and behavioral factors) that need to be manipulated in order to reduce the number of fatalities and serious injuries. Our main challenge is therefore to ensure that all this knowledge is transformed into an action that eventually contributes to a safe road transport system. This moves us from knowledge to policy/innovations to implementation and result. There are various actors who individually and jointly act in the road transport sector, which in the end will affect the operation and the design of the road transport system. However, this implementation and innovation process is not well understood and there is a lack of understanding of the dynamic process that aims to formulate and implement road safety policy/innovations, as well as how road safety interventions are effectively disseminated. Therefore, we need more systematic studies of implementation and innovation processes. Such knowledge would contribute to how safety issues can be solved most effectively and appropriately and thus be of practical benefit to both the individual and the society (Belin et al., 2017).

The implementation of Vision Zero has been largely a trial-and-error process. The state (parliament, government, and authorities, particularly the Swedish Road Administration) played a central role, both directly and indirectly, in the implementation of Vision Zero. With regard to its role as an influencer of different stakeholders, the state must decide whether to intervene or whether to let the market and society take care of itself. Historically, traffic safety work has been focused on management by rules. In the work to realize Vision Zero, management by rules still exists, but occupies less space than in the past. New measures and new approaches were introduced, in which networking and management by objectives are fundamental approaches.

The work to make roads safer to achieve Vision Zero has been primarily characterized by four forms of governance, which have been shown to be effective and have driven the work forward:

- **Management by objectives and results:** In order to create long-term sustainability and a systematic way of working, the Swedish road safety efforts are based on management by objectives. The work includes setting objectives for various indicators judged to have the greatest impact on road safety, for example, adherence to the speed limit, safe roads, safe vehicles, and the use of helmets. Changes to the various indicators are measured, monitored, and discussed at annual results conferences.
- **Network governance:** Collaboration between various parties has been and is a key factor in the work toward achieving Vision Zero. This has led to different parties working together in the same direction through coordination and harmonization. Especially important is the collaboration between the vehicle industry and road authorities.
- **Benchmarking:** The market's demand is the mechanism that governs development and results. This way of working has had good results in terms of safer cars such as Euro new car assessment program.
- **Evidence-based work to improve road safety:** Implementing new road safety measures requires fundamental information about the problems that need to be solved. There are two sources of statistics and knowledge about road deaths in Sweden: Swedish Traffic Accident Data Acquisition (STRADA) and the Swedish Transport Administration's in-depth studies of fatal accidents. STRADA is an information system containing data about injuries (collected through hospitals) and accidents that have occurred in the road transport system. All these methods are examples of processes that are vital to make things happen.

Vision Zero—Outputs and Outcomes

In Fig. 3, we see how the number of fatalities per million inhabitants has developed since the adoption of Vision Zero. In 1999, the Swedish government launched an 11-point program for Vision Zero and based on this several interventions have been implemented: traffic calming in urban area, 2 + 1 roads, new speed limit system, and a large-scale traffic safety camera program, and safer vehicles among other things (Strandroth, 2015). The number of fatalities per 100,000 inhabitants has been reduced from 6.7 fatalities in year 2000 to 2.8 fatalities in 2010, a more than 50% reduction. Vision Zero is a policy and innovations and interventions based on this have contributed to the reduction of fatalities by more than 50% during the 10-year period. This is nothing short of an outstanding result, especially for a country that already was performing well in an international perspective. This is promising because it shows that continuous improvements of both strategies and interventions can help us to get better performance. However, in recent years there are some signs that Sweden has reached a plateau and during 2018 it was even an increased number of fatalities.

During 2009 and 2010 the government made major changes to the governmental structure of the transport sector. Among other things, the Swedish Road Administration and the Swedish Railway Administration were merged together into the Swedish Transport Administration. A new regulatory government body was also set up—the Swedish Transport Agency. However, the government did

Figure 3 Number of deaths in road traffic accidents per 100,000 population in Sweden (1997–2018).

not decide which authority should be the leading agency and responsible for maintaining and developing Vision Zero. In 2016, the Swedish government decided to renew its commitment to Vision Zero and they also decided that the Swedish Transport Administration has the overall responsibility for managing and coordinating the road safety work in Sweden. Hopefully, after a few years of stagnation, through the government initiative to renew Vision Zero, Sweden will enter a new era in the work with traffic safety. Despite a continuously traffic and population growth, Sweden has a down-going trend of fatalities since late 1960s, which is impressive. However, there is still a long way to go until we have reached a safe road transport system where we have eliminated all fatalities and serious injuries and even then the remaining challenge will be to maintain a safe system.

Introduction

Although development of new tire materials, improvement of structural integrity, and tread design over the past decade have helped with improving tire and hence vehicle safety, the number of accidents per million vehicle miles traveled, has not changed drastically. National Highway Transportation Safety Administration's (NHTSA) Crash Causation Survey found that there was an issue with a tire before the crash occurred in 1 of 11 crashes (9%). Issues included tread separations, blowouts, bald tires, and under-inflation (Choi, 2012). They found that:

- Of the tires that were underinflated by more than 25% of the recommended pressure, approximately 10% were in vehicles that experienced tire problems in the pre-crash phase. In contrast, among the correctly inflated tires, a much smaller percentage (3.4%) belongs to vehicles that experienced tire problems. Thus, under-inflation is not the only cause of tire problems; however, when tires are underinflated by 25% or more, tires are three times as likely to be cited as critical events in the pre-crash phase.
- With at least one or more tires with lower tread depths (between 0 and 4/32"), vehicles experienced tire problems during crash occurrence significantly more than chance. Of tires with tread depth in the range 0 to 2/32", about 26% were in vehicles that experienced tire problems in the pre-crash phase while only 8% of tires with tread depth in the range 3/32–4/32" were in such vehicles.
- The percentage of vehicles experiencing tire problems is significantly higher among vehicles that rolled over as compared to vehicles that did not roll over for all vehicle body types: passenger cars, pickups, SUVs, and vans. Of all SUVs experiencing tire problems in the pre-crash phase, 45% rolled over. For the other body types (passenger cars, pickups, and vans), fewer than 25% of the vehicles experiencing tire problems rolled over. Thus, tire problems experienced in the pre-crash phase were more likely to result in a rollover in SUVs than in other vehicle types.
- A significantly higher percentage (11.2%) of vehicles were observed to experience tire problems when one or more roadway-related factors (e.g., wet road, road under water, slick surface) were present in the pre-crash phase as compared to when no roadway-related factors were cited (3.9%). Thus, the vehicles running under adverse roadway conditions may become more vulnerable to tire problems.

Aside from durability issues related to the findings in (Choi, 2012), for all vehicles leading to a crash, lack of tire force and moment generation capability, for the given condition, was the cause of all accidents. For example, pressure difference between the tires located in front of the car, as compared to those in the rear, could initiate and oversteering condition, which leads to instability of the vehicle and potential accidents.

In the current chapter, tire safety is viewed and discussed as force and moment generation capability of the tire and its effects on vehicle stability for studded, runflat (extended mobility), and non-pneumatic tires. Interested readers are directed to [Gent and Walter \(2006\)](#), Chapter 15, where, tire safety, durability, and failure have been discussed and analyzed in details. The analysis provided in [Gent and Walter \(2006\)](#) is mostly concerned with tire failure and its effects on safety. As stated by the authors, performing a failure analysis on a tire is a scientific process that begins with an understanding of the product, including its materials, mechanics, and operational characteristics. Therefore, elements of tire safety, basic mechanics, and factors pertinent to tire durability, including common tire failure modes and analysis are discussed.

Since tires are the only means of contact between the vehicle and the road, they are considered as one of the safety critical components of the vehicle. Aside from tire durability/failure, which can be due to various internal or external issues, forces and moments generated by the tires play the most important role in vehicle stability and safety. Tread separation and blowout are direct durability issues, under-inflation affects both durability and force and moment generation capability of the tire, and bald, studded, and runflat or non-pneumatic tires affect force and moment generation capability, and hence safety of the vehicle.

Figure 1 Longitudinal force/friction vs. slip.

Tire Parameters Affecting Force and Moment Generation Mechanism

During vehicle motion, aside from the ride characteristics of the tire, which are mostly determined by vertical force (dynamic load), tire longitudinal, and lateral forces are the only means for the vehicle to accelerate, decelerate, and negotiate curves. This determines vehicle acceleration potential, stopping distance, and turning accuracy. If these forces are not generated properly, the driver's chance of controlling the vehicle is reduced drastically. For a properly designed and selected tire for a given vehicle platform, tire inflation pressure and tread depth are among the most important factors effecting force and moment generation and vehicle safety.

As can be seen from **Fig. 1**, vehicle speed and road surface have paramount effects on tire longitudinal force generation, which is essential for vehicle stopping and accelerating. As vehicle speed increases from 40 to 60 km/h and road surfaces changes from dry to wet, the coefficient of friction drops nearly by 50%. Therefore, road accidents are more likely to occur on wet and slippery roads than dry road surfaces. This mainly can be defined as skid resistance resulting in friction force that is required for stability and control of the vehicle travelling on the road. Federal Highway Administration estimates that there are, on average, over 5,748,000 vehicle crashes each year. Approximately 22% of these crashes—nearly 1,259,000—are weather-related. The vast majority of the weather-related crashes happen on wet roads—either wet pavement or during rainfall—73% on wet pavement and 46% during rainfall. According to the FHWA report, over 900,000 crashes occur on wet pavement and nearly 600,000 car crashes occur when it is raining. Over 350,000 persons are injured and nearly 4500 persons are killed in the wet pavement crashes. Over 225,000 persons are injured and nearly 2800 are killed in the car accidents which occur during rain (Karzan and Noorance, 2017). Although **Fig. 1** shows that friction reduction between the tire and road on wet surfaces could be viewed as the main cause of accidents, however, this depends on the tire tread design, surface texture, depth of water, and human error.

The data shown in **Fig. 1**, is collected under proper tire inflation pressure. If the pressure is reduced below 25% of recommended value or drastically increased, the force and moment generation capability of the tire changes, leading to vehicle instability.

One of the most influential tire safety parameters is tire inflation pressure. The air inside the tire determines its performance as well as safe operations. In addition to driving with low pressure tires, which can be dangerous and even fatal, tire pressure changes the tire stiffness which in turn effects force and moment generation. When a tire is underinflated, the sidewalls will flex out farther than usual. This will change the effective rolling radius of the tire and can generate excessive heat which may cause tire failure. Additionally, studies have demonstrated the relationship between tire pressure and slip ratio. Slip ratio is defined as the relative

velocity between the tire and the road and is one of the main variables in longitudinal tire force generation. Antilock braking system (ABS), is a control system designed to prevent wheels from losing tractive contact with the road surface by modifying driver inputs during the braking process to prevent wheel lock up (Li et al., 2015). There are many different variations of control methods in ABS. Several involve the comparison of current wheel speed against some constant threshold value. This value is targeted to keep the slip ratio close to some optimal value where longitudinal braking force is maximized. It has been shown that decreased tire pressure increases the peak longitudinal force, but at a lower optimal slip ratio (Besselink et al., 2010). Additionally, variations in tire pressure can change the effective wheel radius by as much as two centimeters over a normal range of operating conditions (Schmeitz et al., 2005). A study by the National Transportation Safety Board (https://www.nts.gov/safety/safety-alerts/Documents/SA_044.pdf) found that underinflated tires lead to over deflection, that is, a change in the tire's radius that is beyond the intended operation limits, which lead to tread separation and ultimately in tire failure that resulted in fatalities. Further, it is also known that underinflated tires experience severe flexing which results in elevated temperatures particularly at high speeds and during hot weather which also results in tread separation and then sudden blowout (<https://www.nts.gov/safety/safety-studies/Pages/SIR1502.aspx>; <https://www.aacar.com/library/tirefail.htm>).

Looking at the vehicle stability from understeering viewpoint (understeering is a stability term used in vehicle dynamics, which refers to the difference between the turning potential of the vehicle front end as compared to the rear end of the vehicle), having less pressure in the rear tires can initiate an oversteering effect, which will initiate vehicle instability during turning at higher speeds. Therefore, tire pressure has multiple effects on vehicle performance and stability. Overinflated tires will result in a smaller contact patch which may adversely affect the force and moment generation of the tires leading to potential stability issues.

In order to eliminate some of these safety related issues, non-pneumatic and runflat or extended mobility tires were introduced. Although currently there are not any non-pneumatic (Tweel: <https://michelinmedia.com/tweel/>, for example) tires in use under passenger cars, they are being developed as a viable option to replace the pneumatic tire.

Studded, Runflat and Non-Pneumatic Tires

Studded Tires

Regarding studded tires vs. non-studded, there are several issues which have resulted in several states banning the use of these tires. A study conducted by Washington State Transportation Commission (Scheibe, 2002) concluded that:

1. Studded tires produce their best traction on snow or ice near the freezing mark and lose proportionately more of their tractive ability at lower temperatures than do stud-less or all-season tires.
2. The traction of studded tires is slightly superior to stud-less tires only under an ever-narrowing set of circumstances. With less aggressive (lightweight) studs being mandated, and with the advent of the new "stud-less" tire, such as the Blizzak, since the early 1990s, the traction benefit for studded tires is primarily evident on clear ice near the freezing mark, a condition whose occurrence is limited. For the majority of test results reviewed for snow, and for ice at lower temperatures, studded tires performed as well as or worse than the Blizzak tire. For those conditions in which studded tires provided better traction than stud-less tires, the increment usually was small.
3. Traction performance can be characterized in many ways, including braking, acceleration, cornering, controllability, and grade climbing. Though all factors are important, the single best indicator of tire performance is braking distance and deceleration. Studded tires reduce the difference in friction factor between optimum-slip and locked-wheel braking in comparison to non-studded tires. This may reduce the risk of drivers misjudging the necessary braking distance and may improve the braking potential for anti-lock brakes. In one set of stopping distance tests in Alaska, studded, stud-less, and all-season tires performed nearly equally on snow, when averaged across several vehicles. On ice, stopping distances for studded tires were 15% shorter than for Blizzaks, which in turn were 8% shorter than for all-season tires.
4. On bare pavement, studded tires tend to have poorer traction performance than other tire types. This is especially true for concrete.

Although all of the conclusions drawn from this study are related to longitudinal performance of the tire/vehicle, the lateral performance on dry surfaces can be degraded due to the nature of contact and the friction coefficient associated with material variations and less apparent area of rubber contact with the road. Fig. 2 shows the comparison between the longitudinal force of studded and non-studded tires (Ivanov et al., 2017).

Run-Flat Tires

A run-flat tire is a relatively new concept that has begun to integrate itself into modern vehicles. Rather than a standard tire, a run-flat tire has a polyurethane ring that allows the vehicle to remain driving after the tire loses all its pressure. The polyurethane ring is offered as a security blanket to drivers in case they run into issues with the tires. Run-flat tires have two basic designs: one with a sturdy sidewall and one with a stiff inner ring. With a standard flat tire, a driver must pull over immediately. This is because the weight of the vehicle on the rims of the wheel can cause serious, costly damage and make driving conditions unsafe. Drivers will also experience unpredictable steering. Run-flat tires are designed to keep drivers on the road safely for longer periods of time in the event of a blowout. The tires rely on strong reinforced sidewalls to support the weight of the vehicle if the tire is punctured or loses air pressure. The sides of the tire are thick enough to carry the vehicle for miles without damaging the wheels or suspension. Another type of run-flats has a tough and rigid ring inside of the tire, hugging the wheel. When these tires lose air pressure, the ring spins on

Figure 2 Longitudinal friction coefficient for studded and non-studded tires (Ivanov et al., 2017).

the road rather than the wheel rim. The miles of allowed driving distance let drivers find a safe spot to pull over to the side of the road and change the flat tire. However, many cars that are equipped with run-flat tires do not have spare tires, which means that a mechanic with a new tire must be called to the location.

Though runflat tires provide a great advantage over a completely flat or significantly underinflated tire, their characteristics do vary significantly from an inflated tire in normal conditions. For example, a runflat tire compared to a conventional tire each at a vertical load of 9 kN demonstrates a 45%–50% greater vertical stiffness. The vertical load is more comparable for loads under 3 kN. This will lead to a rougher ride as compared to regular tires. Additionally, runflat tires will exhibit degraded handling performance at higher speeds and could be a safety concern if transient steering inputs are commanded by the driver.

Non-Pneumatic Tires

In addition to runflat tires, which behave very similar to regular tires while fully inflated, the non-pneumatic tires have been studied for the past two decades. Tweel, a Michelin Tire Company product, was introduced as a concept in 2005 and was offered as a product for use on loaders in 2012. Once offered for passenger cars, these tires have the advantage of not requiring to be inflated and hence tires will never be flat or fail due to puncture. Researchers have been trying as long back as 1920s to build a non-pneumatic tire (NPT) that has sufficient resilience (Cozatt, 1924). With advancement in material science and manufacturing technologies, researchers were able to create NPTs having sufficient compliance (Rhyne and Steven, 2005). Modern NPT designs integrate wheel and tire into a single component. The NPT consists of a rigid hub, flexible spokes, shear band and tread which is made up of rubber.

What are Town Gates?

Historically, town gates were used for protection of cities, towns, and villages against invaders. They were also used as a location for collecting tolls related to people or products. With the enlargement of cities, old town walls and gates can nowadays often be found toward the center of large cities. For transportation, modern town gates are of importance to prevent injury or accidents by informing people with the use of signs or other information at the entry to the town so they behave safely for themselves and for others. The information aims to engage mainly drivers that they are entering or leaving a place where other people live; thus a place with specific risks of conflicts and dangers and rules for avoiding these dangers. The importance of information from town and village gates increases with the degree of the transition from outside to inside the town or village. If a high-speed road is going through a village, seeing, paying attention to, making smart decisions, and reducing speed according to mandatory rules of traffic regulations are important in order to avoid accidents and reduce their severity if some accidents still happen, with a goal of especially avoiding fatal injuries.

To behave properly, people must know when they are entering or leaving a town or a village. The context, such as denser housing, might be of help but it does not guarantee that all drivers note that they have entered an urban area. Legal and safe behavior can be obtained to a great degree by using and getting compliance to traffic signs and road markings. When entering and leaving towns, there are specific international road signs indicating the perimeter of the compact area, so called town gates, although there may be no gates at all, just traffic signs for entrance and exit (Fig. 1). Such signs are sometimes labeled "Traffic Calming Signs" if they have the aim of slowing the flow of traffic entering the built-up area. Some communities also use non-conforming gates, which may resemble medieval gates or modern "portals" with structures spanning across the roadway at a height allowing vehicles to travel under them.

As for any road and traffic sign, Traffic Calming Signs are external representations using symbols and or text that should be matching all local and national regulations that drivers are supposed to know, to remember and to apply. Thus compliance to in-town and village traffic regulations is not solely a matter of perceiving the sign that indicate gates, but a matter of knowledge, and of interpretation based on a less or more precise cognitive model of situation about being inside this specific town or village. It follows that foreign visitors might be less aware of local rules and comply only according to their own habits. For instance, a foreign driver from a country where school starts at 9:00 a.m. might pay less attention to warning signs for schools when it is 5:00 a.m. in the morning although in the actual country school may start at 5:30 a.m. Thus, departments responsible for city infrastructure should be aware of how to inform visitors, and people just passing through, about road safety and security and make sure people understand the meaning of local road signs.

To communicate with drivers and obtain good traffic safety in towns and villages, motorists must be made to understand what is going on inside the town gates. Such an understanding is based on the "where," "who and what," "when," "why," and "how" dimensions of events and actions made by people who live there. Such knowledge activation or provision of new information is useful and can be provided through tourist's brochures, new traffic regulations, installation of road regulatory signs and road markings, and of the improvement of roads and streets by using traffic signals, roundabouts, and geometric features such as humps and pedestrian pathways (de Lavalette et al., 2009).

Figure 1 Traffic signs indicating (A) for any kind of Town gates with entry on top and exit on bottom panel, (B) for a village named St Vincent de Tyrosse with entry on top and exit on bottom panel, and (C) for entrance of a village named Elkington with a 30 km/h speed limit.

By providing guidance on logical and clear transportation information and regulations before, at and behind town gates, we expect this article to be of help for the design of regulatory procedures, rules and information signage and finally of help to improve safety for drivers, bicyclists, and pedestrians in general and in particular for specific users such as tourists or children, as well as people with disabilities including accessibility for the elderly, for example, when crossing streets. To do so, we first provide the logic of activities and other things inside town gates, the logic of action and behavior that are based on the nature of things inside towns, and how the regulatory authorities of transportation inside towns are delivering the information about obligations, prohibitions and permission by externalizing them in signs that everyone can understand.

The Logic of Things Inside Town Gates

When traveling from outside town gates to inside a town, there is a number of informational items dedicated to transportation through the town, including announcement of the town entrance (Fig. 1). There are roads and streets, some with and others without sidewalks, some that bypass the city, and some of those may be limited-access highways, others that go through the town and may be intentionally narrowed in width, with speed humps, a number of roundabouts or traffic signals, or both. In addition, one will find much information for drivers of passenger cars and of trucks, mostly on traffic signs. These use physical entities to encourage or force the desired driving behavior or remind road users of the driving rules. But most important are what is not displayed but is supposed to be known. For instance, inside town gates, in many countries, the speed limit is set at 50 km/h, unless there is another more restricted limit (such as shown in Fig. 1C).

In addition to purveying knowledge attached to town gates, there is rationality to how people should behave inside the gates. Transport safety and security depends on the understanding of this logic of functioning and of utilization of the city while traveling.

Who

To obtain safety in transportation, motorists should be able to easily imagine the kind of people who live in a place: unpredictable school children, slow walking aged people, joggers that avoid stopping, bicyclists are some groups that can be expected. To do so, drivers need to pay attention to the traffic signs that provide information about people who live or spend time at a location.

Where

To obtain safety in transportation, motorists should have a good representation of the structure of places inside the town. The city can be with or without an increasingly populated city center in which going downtown will provide places with more and more people, markets, tourist destinations, shops, and traffic congestion.

Visitors should know where to find useful locations (e.g., restaurants, parking lots, toilets, etc.) as well as specific locations such as hospitals, schools, and train stations and so on. Along streets, one should be able to find indication of what exists in the town (i.e., a hospital sign) but also in which direction to go to find WHERE is a special place (i.e., a sign with an arrow indicating where to go to find a hospital and distance to it). For instance, Fig. 2 indicates buildings that are located where the road signs are placed, here or further away.

When

Transportation information is mostly permanent information. For instance, information about how to behave (e.g., *do not bypass; speed limit, etc.*) is delivered with road signs that indicate that at any time drivers may behave that way. There is some information about WHEN. And if so, this is information about which days in the month (*No Parking from the 1st to the 15th of the month*), which day in the week (*Friday to Saturday*), at what times (*11 p.m. – 5 a.m.*), and sometimes how long (*2 hours limit*).

Figure 2 Road signs indicating the kind of building that exists there (left panel: a school, middle panel: a hospital) or which direction to go to find a kind of building (right panel: a hospital).

Why

WHY is about the understanding of the meanings of things inside town gates. For instance, Fig. 2 indicates buildings inside the town: a school here, a hospital here, and a hospital further away. The related action, —the reason why these road signs are placed there—, is

- for the school sign (Fig. 2, left panel) about increasing drivers' attention and precaution because of the danger (red triangle) that corresponds to a place frequented by children going to and from school, an increasing risk according to the school schedule,
- for the hospital here (Fig. 2, middle panel), the location of a hospital is indicated but it should be known that this is for non-emergency services, or a clinic. In case of an emergency, going there by mistake can be fatal in case of a serious injury,
- for the Hospital further away (Fig. 2, right panel), this is indicating a hospital providing emergency services (indicated by the red cross) and it is mandatory (blue background of the sign) to go in that direction to find emergency medical help.

It appears that transport safety depends not only on the pertinent and efficient implementation of regulatory traffic signs, but on the knowledge of road signs by people using the streets in the city, on their interpretation of what to do according to their understanding and misunderstanding of the whole transportation system implemented in the city and finally implications of this on their decision making.

How

Safe and secure transportation within a city depends on HOW people behave while interacting with others. This is influenced by their knowledge, expertise and familiarity with things inside the town gates, and the implementation of support of displayed information. Let's look at one of the worst scenarios based on incorrect decision-making: A child is running to school because s/he is late. A driver who does not respect the danger sign indicating "place with children going to or coming from school" (Fig. 2, left panel) runs into the child and takes her/him to the hospital located here (as indicated in Fig. 2, middle panel) instead of taking her/him to the hospital for emergencies (Fig. 2, right panel); a hospital which he can then have difficulty finding because he does not know which direction to take; not being reminded where the direction indicator sign was, although it was seen.

Note that in such cases, expertise can help; by heuristics: to find a sign that we have seen, take the same path that allowed us to see this sign earlier; but better to call an ambulance by using a mobile phone or from the nearest emergency telephone.

In summary, HOW people behave depends on their decision-making according to their understanding of WHY things in town function in a certain way according to WHO, WHERE and WHEN. These dimensions are those that are constraining actions: what one can do, and what one cannot do.

The Logic of Action Constraints Inside Town Gates

In a majority of countries, most people live in towns and villages. Contrary to motorways for which much of information and mandatory rules are focused on automobile regulations, inside town gates, much is about interactions between people in cars and people outside cars. Thus, the logic of expected behavior relates mainly to people in or out of cars. For people inside cars, there will be information about how to drive; and also, where to park, locations of services, tourist places to visit, and so on. What should be known is that this information inside town gates increases both in informational and procedural levels of complexity. Knowing this improves safe and secure transportation by anticipating next steps of interaction with the inside town gate system of delivering services and regulation information.

The Overall Logic of Action Constraints in Town

There has to be a logic to transportation information. Knowing this logic improves safety. The logic helps understand where signs should be placed in towns. The purpose of signage is to indicate, in iconic or linguistic form, places, directions, actions, or

Figure 3 Road signs indicating action prohibition for different kinds of objects, respectively in left panel: not crossing without stopping at an at-grade railroad crossing, middle panel: not entering a street in that direction, right panel: do not park.

prohibitions of actions in the city. In fact, there are no other uses of signage than indications of objects (O), properties of objects (P of O), actions (A on O to change OP), prohibitions of action (Don't do A on O), or cessation of action (now you can do A on O) on objects or categories of objects. Following are the successive levels of difficulty:

1. the indication of an object ("this is O") or of a category of objects ("this is a kind of O") such as a panel on which is written "North Station" or "station," or as another example "pedestrian crossing,"
2. the indication of object properties ("O has this property P") such as the information according to which "this station is the bus station" or that "this pedestrian crossing is taken by children,"
3. the indication of action to be undertaken on an object property ("Action A allows you to transform this property of O"), such as the sign informing that going in that direction will reduce the distance between where you are and the bus station, or indicating that slowing down the speed of the car will increase the level of safety at the pedestrian crossing,
4. the indication of procedural sub-goals ("How to use O"). For instance, such as how to use the train at-grade crossing: "Always approach the at-grade crossing carefully and be prepared to stop. You must obey the traffic signals. When the amber or red lights show, you must stop behind the white line across the road. If you have already crossed the white line when the amber light comes on, keep going,"
5. the indication of prohibition of actions on an object ("Action A on O to change P is prohibited), such as signs indicating not crossing without stopping at an at-grade crossing, not entering a street in that direction, do not park (three prohibition corresponding respectively to the left, middle and right panels of Fig. 3), and
6. the indication of cessation of prohibition of actions concerning the ownership of an object ("Action A on O to change P is no longer prohibited), such as signs indicating that there is no more parking prohibition or indicating that there is no more prohibition of any kind.

Note that any given level implies the preceding. For instance "now you can park (f)," implies that "before it was not possible to park – e" (and maybe it will not be possible again to park later), that there are "subgoals to park – d" (entry, parking ticket, find a place, keep parking ticket with you, etc.), implying in turn "you can park your car on one of the free parking place, reducing the number of free parking places – c" implying the information about how much free parking places – b", implying the indication of this is the parking- a".

Finally, note that in addition to prohibition of actions and of cessation of prohibition of actions, you might get the reverse such as indications, permissions and obligations of action.

Externalization and Internalization of Transportation Information

Road signs in town are externalization of rules in the real world for safety and security. The transportation regulatory authorities expect that when people in town (drivers, passengers, pedestrians, etc.) see the content of a sign in its external environment, by processing this content (seeing, categorizing, reasoning, and interpreting), they will internalize its meaning and will take the correct decision. Thus, when a driver sees a pedestrian crossing sign, s/he will pay attention, reduce speed while the pedestrian will respect the corresponding rules by using the pedestrian crossing and doing so in a safe way. Driver-pedestrian interactions are to be regulated that way. However, signage is not solely indication of action to do or not to do, signage also has semantics. It is symbolic in nature so that the meaning of a road sign, or of a pictogram is not unequivocal. It therefore requires an interpretation largely based on the context, and here the context of the town. For this reason, in line with the work on ergonomics on the understanding of technical notices, work on semiotics and applied linguistics, the semantic analysis of signage is essential.

An action that is to undertake or not on an object because this object belongs to a specific category of objects according to this action. For a safe and secure transportation in town, it is of importance that people get the proper meaning of signage in town (Bazire and Tijus, 2009). For instance, most people are often mistaken what a road sign means because it is not explicit but implicit. In the

Figure 4 The possible misinterpretation of signs in town, when the sign is displayed on the surface of the street, when trucks are passenger cars, when cigars and pipes are cigarettes, when don't kiss means that "the departure of the train should not be delayed."

left panel of Fig. 4, a road sign indicating a speed limit (50 km/h) is directly drawn on the surface of the street. A driver might say that this is indicating that he has to drive his car at 50 km/h, which is not true. The proper meaning is that vehicles must keep a speed below 50 km/h at all times, and, most importantly, because we are inside town gates, for any street not posted, the speed limit may be 40 km/h in this country. Thus, the next street will have the same speed limit although there could be no sign displayed to remind this rule.

In towns, there are often narrow streets, and there is sometimes a sign about prohibition to overtake other vehicles. In countries following the Vienna Convention of signage, this is shown by displaying a red pictogram of a passenger car to indicate that it cannot overtake another passenger car or a red pictogram of a truck to indicate that trucks cannot overtake cars (Fig. 4, middle panel). First, these road signs may be used because roads are narrow or there are other reasons we do not want drivers to pass other vehicles. Second, the pictogram of a passenger car does not apply solely to passenger cars but also to trucks. And the truck that cannot overtake a passenger car also cannot overtake another truck. All drivers should know that the pictogram of a passenger car designates passenger cars as well as trucks while the pictogram of a truck designates only trucks but not passenger cars. However, drivers from for example the United States may not understand this since they are not used to Vienna Convention signs.

Outside of town centers, for example in a forest, a sign can be showing the pictogram of a cigarette with a slash across it (indicating a ban, as in the right panel of Fig. 4). The meaning of the sign is that forest fires should not be started by smokers. When the same signage is used in a town, its meaning is that people should have their clean air unpolluted. More important for understanding is that although the pictogram on the sign is a cigarette, in both cases, smoking a pipe or cigar is also not allowed. Misunderstanding could be more pronounced when the pictogram is used in a metaphorical way. For instance, the prohibition sign of "kisses" (the drawing of a man and a woman kissing, all crossed out by a slash), which was found for a while on the platform of a train station in UK could be mistaken as meaning that a man and a woman are not allowed to be kissing each other, whereas two women or two men could. The meaning was that, "The departure of a train should not be delayed by people taking long good-byes," and among all the possible situations that could delay the train departure, the administration of regulatory signs chose this example.

Note that for blind or deaf pedestrians, providing specific information, for example at pedestrian crossings, are often provided: marking on the ground sensible for the blind man's cane with synthetic voice; or flashing lights to compensate for loss of hearing (Tournier et al., 2016).

How to Favor Correct Decision-Making in Towns: Recommendations

To make people properly follow rules that arise from entering a city, the regulator must have two principles of transport ergonomics in mind. The first principle is based on a general distinction between system and user-centered design (Norman, 2005). The second principle is the distinction between metaphorical display categories and specific target categories (Tijus et al., 2007).

The first principle is that legal categories which define what concerns transportation and road safety may not correspond to the natural categories of people. As an example, we can consider, as in Fig. 4-middle panel, the truck that is a passenger car because all of the regulations that apply to the passenger car also apply to the truck (the reverse being not true). If this implication "trucks are cars" works in the case of prohibition, it should be noted that in case of permissions, or even worse in case of obligation, people can misunderstand the intent and reason that "if it is allowed for drivers of passenger cars, then it should be allowed for trucks too!" Thus, one is to be advised that the categories of behavior to regulate might not match the categories of the users' behaviors that need to be regulated. The legal categories may concern, for example, the use of traffic lanes and sharing them between different types of users while the users concern may be the things to be transported using vehicles in the traffic lane.

The second principle can be illustrated with an example such as the "two people kissing" category, as instantiated in Fig. 4-right panel, not to indicate that kissing is forbidden but to signify that "the departure of the train should not be delayed." However, people might have a literal interpretation: not kissing while delaying the train departure!

Signs, traffic signal displays, pavement markings, refuge islands, and demarcations the kind of information that might be affected by user-centered recommendations: on the one hand, to avoid using regulation categories instead of what is natural categories to people, and, on the other hand, to avoid using misleading analogies or pictorial metaphors that might not be matching the categories of the regulation. Note that the balance is to be provided by the goal of what legal behavior is to be attained.

The overall recommendation is to be careful with respect to the where, who, when, why, and how.

Being careful of where. For town gates, the main distinction is between the “urban built-up area” and the “outside urban built-up area.” The built-up area is defined as “the space where buildings are grouped closely together.” Its limits bounded by entrance signs and exit signs are usually defined by decision of the city council or mayor. In Europe, all permanent signs must comply with a certification using the CE marking regulation (European Conformity: European standard). The cluster of entrance and exit signs is placed along the lanes. In France, for example, these are EB panels: EB10 for the entrance panel and EB20 for the exit panel. They are designed for best visibility, especially at night, to signal to drivers that they are entering or leaving an area of concern. The road sign panels are important because they indicate the urban built-up area is the area within which the rules of driving, and police as well as town planning rules apply. However, care must be taken to avoid confusion because the location of the sign does not correspond to the real limits of the municipal territory. The road signs for entering the municipality is also of importance: it designates a transition zones from a high-speed area to a low-speed area with an increased risk of accidents, injuries and deaths (Lantieri et al., 2015).

Being careful of who. The city’s transportation regulator designs the way people will be using the town and will be using the displayed information that are provided about some of the city’s parts. In a user-centered regulation of inside town transportation, the regulator should be aware of the most usual mental representation, schemas and scenarios people use to drive themselves to enter the town and to travel inside, mainly for those that are unacknowledged about the city, such as tourists or those that are just passing by. For instance, people do have often the following mental models about a town: (1) shortest way to cross it is to go straight on, (2) main important monuments, markets, shops, parking lots and toilets will be located in the city center, (3) the city center should be crowded, and so on. Thus inquiry about who is using the town is to be the first step of an efficient transportation regulation for taking into consideration the opposite usages of the transportation means (e.g., pupils vs. drivers in hurry). Thus, traffic signs should provide information about locations and about people who live there.

Being careful of when. Inside towns, people’s typical activities are time related. Consequently, a number of permanent sign panels deliver information about when and for how long a transportation action can be executed (allowed to park here for a maximum of one hour from 10:00 to 12:00). Note that the “when/where” dimension, except for variable message signs used in “smart cities,” is a difficult regulation due to a combination of space and time constraints. A permanent sign panel is location-based. It is fixed all the time in a specific location and need a point of view and a maximum distance from where it to be seen by a viewer. If the displayed information is relevant all the time for the whole area of the town (e.g., speed limit), a single well-situated localization may be sufficient, and it should be properly seen every time it is passed. In opposite, time constrained regulations displayed on permanent sign panels are useless at times they do not apply. In addition, time constrained regulations are usually location constrained to a specific area, thus should not be displayed elsewhere. Consequently, the permanent sign panel has to be displayed in the right target place (e.g., to a square is free from parked cars when it is to function as a vegetable market place every Monday from 6:00 to 16:00).

Being careful of why and how. People follow a rule better when they understand its rationale in terms of a simple mental model. Very often, the reason for a rule is either known or implied and the purpose of sign panel is primarily to serve as a reminder. For example, Fig. 4-left displays the 50 km/h speed limit, which applies to the whole town. This sign is located where it can remind drivers, for example because a forest environment could negate the suggestion of being in a town. In opposite to the “why” dimension that relates to the understanding of the situation, the “how” dimension is to be developed and apply here and now as real actions in the current situation. Not knowing how to act is a potential dangerous situation. And because transportation regulation is in the form of “DO NOT DO,” a user that is confronted with the “DO NOT” constraint although s/he was going “TO DO IT” is facing a problem. The city’s transportation officials should be aware of providing a possible solution. For instance, if the constraint is “not to park here in order to free up a square to function as a vegetable market place this Monday from 6:00 to 16:00,” a sign indicating where else to park would be of benefit.

Conclusion: Future Uses of Town Gates

Instead of delivering information by signs, city ergonomics might be the futures where a city does not use written or pictorial instructions. Instead, the design of a smart city may be to go to providing a contextual and connected user.

First of all, following human-centered design concepts of transportation regulation inside the town gates, is designing the “what You See Is What You get” (WYSIWIG) ergonomic environment of the town. For instance, rather than using speed limits sign panels at the current town gates, at the entrance to the city, at the location which is the dangerous transition zone from high-speed areas to low-speed areas, physical measures can be used. The gateway to enter the city can instead be made of chicane deflections, bulb outs, and of wide central islands that narrow the lanes and indicate by sight a safe speed limit to drive. Vertical elements and portals can also be used. Thus, the speed limit is not delivered by signage to the user’s observance but in the physical situation.

Moreover, rumble strips and speed-activated humps in the road can cause the car and thereby the driver to tremble when the car is moving too fast or when it is not well positioned laterally. The driver’s body thus directly participates in the regulation of transport. These are promising solutions.

The next step is using smart town gates related to a connected transportation mode. This Internet of Town Gates can provide digital sign panels inside the vehicle instead of having the driver look outside the transportation mode. This can be done with connected or autonomous cars, buses or trains and can provide their users the information they need when they need it. More useful transportation regulations can thereby be providing the how-to-do-it and why, with consideration of time constraints, if any, to the target person, about what is where.

Biography

Charles Tijus heads the Cognitions Humaine et Artificielle Laboratory (CHArt), a Cognitive Science laboratory and the "Laboratoire des Usages en Technologies d'Information Numériques (FED 4246 - LUTIN), a Living UserLab located at the "Cité des Sciences et de l'Industrie" in Paris, France. Charles Tijus' PhD was on "visual memory span of 3D objects." As a Research Assistant, he has worked on visual perception with Adam Reeves (Vision Lab, Northeastern University, Boston, United States). He currently develops a contextual categorization-based approach to model the cognitive processes of understanding, decision-making, and learning. In the transportation research field, this is about road signs taxonomy, understanding pictograms as well as drivers and pedestrians' decision-making according to the contextual environment.

Introduction/Overview of the Problem

Modern road transport systems have improved societies by offering increased mobility and connectivity worldwide, especially since the 1950s. Despite these benefits, road safety is an ever-present issue, with roughly 1.35 million deaths occurring every year worldwide from road crashes, which constitute the leading cause of death for people of 5–29 years of age. It has been established that about 95% of all road crashes are caused primarily by human error (Singh, 2015), with the remaining percentage split between infrastructure and vehicle defects.

Factors affecting the risk of human error, such as drivers consuming alcohol or using cell phones or interacting with passengers, have been examined extensively by researchers. It can be argued, however, that traffic flow is a parameter that is tightly knit with human behavior and human error. Not only drivers are prone to changing their behavior based on fluctuations of the number and position of cars around them, ranging from becoming more aggressive or defensive, they also become more exposed to the behavior and the respective variations of others as well. If the traditional features of traffic flow that are utilized in highway engineering, transport system planning and traffic management are taken into account, it can be then assumed that traffic flow is always a relevant and interesting parameter to examine when considering road safety.

Traffic flow is defined as the number of vehicles passing a point per unit of time; it is also often called traffic volume, when the time unit is 1 h. The more straightforward approach is employing the parameter known as annual average daily traffic (AADT), which, as the name implies, is the average number of vehicles passing a point during 24 h measured over a year. This attribute is indicative of the intensity of use of an examined road segment, and can be further refined by lane or by vehicle type. AADT also has the potential of providing a hint for the macroscopic evolution of the state of the road if examined over the course of several years, and can be used to infer road safety impacts of changes in traffic volume, perhaps by interventions from road safety measures.

Other traffic flow parameters, such as hourly traffic flow, volume to capacity (V/C) ratio also known as degree of saturation and similar proxies of congestion, have also been considered in the past. All the aforementioned parameters, however, express aggregated quantities that have the drawback of being somewhat static and not reflecting the precise flow at any given time, especially when

compared to the alternatives offered in recent years of real-time data, big data, and intelligent transport systems (ITS). A disaggregated parameter with higher temporal resolution, average daily traffic (ADT) is a step between AADT and microscopic data. ADT has been implemented by researchers to gain more precise background than AADT in road safety studies, for instance as described in Wang et al. (2018).

Undeniably, the present and future trend is the use of real-time methods to obtain snapshots of the state of the road environment in a dynamic manner. These methods frequently include data collection through roadside video analyses, vehicle instrumentation, or smart phone sensors.

The aim of this chapter is the examination of the way traffic flow is treated by road safety researchers and also its overall impacts on road safety. The aim of this chapter is not to provide an exhaustive list of studies, methods, and results for real-time traffic safety. For more details about real-time traffic data and safety evaluation, the reader is encouraged to refer to the further reading list of the present chapter. Furthermore, the ever-important parameters of speed and occupancy (occupancy is defined as the time fraction during which a detector embedded in the roadway is occupied, i.e., whether there is a vehicle on top of the detector) warrant separate investigations and as such fall beyond the scope of this chapter. Similarly, parameters such as V/C ratios and hourly flows were not examined here, because when referring to the traditional approach, the most commonly used entity is AADT.

Data Sources

Traditional Approach

Until around 50 years ago, most traffic volume data were collected by roadside observers. These could be researchers or unspecialized employees that would remain by a dedicated road segment and count passing vehicles for predetermined time duration. Considerable care is required during the design of such studies on several fronts; the positions of measurement were important in order to ensure correct vehicle counting. Junctions should be adequately covered in all available entry and exit points. Similarly, the presence of complex road environments, such as ramps, tunnel exits, and junction arms should be taken into account to ensure the correct area is measured every time. The time and date of measurement is critical and tied to the objective of the research, as fluctuations and spikes are the norm: for instance, urban traffic flows are lowered during the holiday season or during nighttime.

Automatic Vehicle Identification (AVI)

Roadside Sensors

As an alternative to manual counting, pneumatic tubes placed across the roadway, typically fastened by hook that is nailed into the asphalt pavement at each end, and connected to a traffic counter, have been used since the 1930s. These tubes do not count vehicles but axles and the results are either presented as axle pairs or as estimates of vehicle numbers based on manual observations concluding that vehicles on average have, say, 2.1 axles at a given location.

An alternative to pneumatic tube that actually can distinguish actual vehicles is using automated loop detectors installed just below the top of the pavement, as those described in Yannis et al. (2014). Though even those may mistake a truck with a trailer for being two separate vehicles. Loop detectors can be temporary but are typically permanent devices installed in a lane or across the entire roadway and function by detecting electro-magnetic pulses when a metal object, such as a vehicle pass over the loop. Similar devices that are installed in proximity to the road surface, rather than on or under it, include radar, video, photocell/infrared sensors, and ultrasound sensors.

Traffic flow measurements were traditionally conducted over 24 h or more, with the counters registering the count numbers by 15 min periods but more modern equipment can record numbers for much shorter time intervals, typically of 30, 60, or 90 s; and more advanced equipment can distinguish between heavy vehicles, cars, motor cycles, and bicycles, thus providing separate counts. Data from roadside sensors can be used in crash analysis to provide insights on the traffic conditions at the time of a crash. One approach includes analyzing the values from sensors exclusively on the crash segment, while alternatively the upstream and downstream values are used in conjunction (e.g., as mentioned in Roshandel et al., 2015).

Video Vehicle Detection

Another method is the real-time analysis of video from traffic cameras to determine vehicle counts. This method is considered cost-effective as it can handle many lanes and directions simultaneously, and furthermore more precise information is available in cases where there is ambiguity or uncertainty in the measurements. Without proper design for minimized computational requirements, however, this method can lead to large and possibly unwieldy amounts of data.

Emerging Methods

Recently, new methods have been emerging in the transport sector for a wide array of applications, including traffic flow counts. These methods involve the use of affordable bluetooth and wi-fi readers that can be installed at road segments with little to no calibration. Alternative systems include utilizing smart phone data from a fraction of participant users and inferring the concurrent traffic flows from these counts.

Data Processing Using Real-time Traffic Data

Real-time Traffic Data Potential

As mentioned earlier, the introduction and rapid growth of ITS have enabled the access to modal disaggregated traffic flow data through the constant monitoring and recording of traffic at the installed locations or specific segments of freeways. Usually these kind of data are provided in very short time intervals, such as 30 s, 1 min, 2 min, or 5 min. Consequently, it has given a unique opportunity for traffic safety engineers and researchers to shift to more disaggregate types of data in order to ultimately explore the traffic conditions prior to a crash. As a result, traffic flow (volume), density, occupancy, speed, and heavy vehicle proportions could be measured. One of the most important research implications is the fact that researchers could not only calculate the total number of vehicles like AADT, but also aggregate the data to reduce noise and capture traffic fluctuations and temporal variability as well. Moreover, the analyses could also be made per lane. By that way, variability among adjacent lanes could also be captured. An illustration of typical traffic flow parameters used in research in different countries is provided in the following.

Sum and Average of Traffic Flow

The sum of traffic is a frequently used traffic-related variable in past literature. More specifically, the traffic volume is usually the sum of vehicles passing a reference point per unit of time, for example, vehicles per 2 min. However, the average value is also a common variable considered in real-time traffic analyses. Let us suppose, for example, that the raw traffic data are provided by the traffic management center of a freeway in 30 s intervals. Then, for instance, when the raw traffic data are further aggregated into 2 min time slices to reduce noise, the average traffic flow can be calculated simply by dividing the total sum of flows by the total number of time slices.

Variance of Traffic Flow

Another phenomenon of interest is the fluctuation of flow, which can be estimated in a spatial or temporal manner. In the former case for a specific time slice (e.g., 5–10 min prior to a crash), the difference in traffic flow values between upstream and downstream loop detectors is usually calculated. In some cases, the traffic flow difference between the crash segment and the upstream or downstream loop detector is also utilized as well. It is noted that if the researcher has access to disaggregate traffic data per lane, then the variability between adjacent lanes is another way to estimate spatial variability in traffic.

Overall, the spatial traffic flow difference expresses the variability in traffic conditions from a specific point to another specific point of a freeway. For example, there can be abrupt transitions from free-flow conditions at one location to more congested conditions at an adjacent location or vice versa. In international literature, temporal and spatial variations are expressed simply as continuous variables. In the spatial approach the produced variable could simply be the mathematical difference of the average flows in a specific time slice.

In the temporal approach in specific, the entity that is estimated is simply the variability in traffic conditions of a specific time slice at a specific point near a crash, that is, in the downstream loop detector. Let's assume for instance, that the raw 20 s data have to be aggregated to 2 min intervals and we wish to calculate the variability of traffic. This could be carried out by calculating the variance and the standard deviation of flow. Lastly, another proxy of traffic variability that researchers frequently resort to is the simple coefficient of variation of flow.

Overall, the aforementioned measures express the variability in traffic. Higher values of flow fluctuations can be translated, as unstable conditions and heterogeneity in traffic flow are often associated with more crashes and also more severe crashes. The variation of traffic flow and the respective impacts in traffic safety have also been examined under varying weather conditions; traffic flow was found to be reduced under fog conditions, indicating increased driver caution (Wu et al., 2018).

Less Frequent Traffic Flow Parameters

An alternative traffic flow related variable that sometimes is used is the median value of flow. Once again, data have to be aggregated in larger time intervals to obtain the median. It is straightforward to estimate the median. For instance, if the number of traffic observations is even, the median flow is calculated as the mean of the two middlemost numbers after the numbers have been ordered from the lowest to the highest. Otherwise, for traffic flow, in the say 20 s intervals, the median will be the middlemost value.

This section ends with the probably least observed traffic flow related variable, namely the chaos index, which expresses the impact of traffic chaos on traffic safety by multiplying the flow with a dimensionless coefficient which is obtained by dividing the speed variance with the average speed. When all cars travel at the same speed, they “take up less space” than the same number of cars traveling at very different speeds near each other.

Additional Issues

Road Segmentation

Another essential step in data preparation is road segmentation that is to divide a roadway into segments. One reason to resort to road segmentation is for assigning crashes to road segments (see also section of Crash Frequency). Another reason is the need to

account for unobserved heterogeneity (see also sections of Crash Frequency and Crash Severity). Generally, two main choices are available: fixed segmentation and homogeneous segmentation.

In the former case, the road network is divided into fixed-length segments, for example, 500 m. The problem with this approach is the fact that the variation in road geometry (e.g., straight segments, curves, tunnels, etc.), is not taken into account. Consequently, the latter approach is preferred in order to achieve the homogeneity in roadway alignment. In general, both horizontal and vertical alignments should be scrutinized. It is also noted that a minimum-length criterion should be generally set so as to avoid low exposure problem and low crash numbers for very short segments. It is therefore suggested that very short segments (e.g., shorter than 100–150 m) should be combined if possible with adjacent segments having similar geometrical characteristics.

Precise Crash Time Estimation and Correction

In real-time safety evaluation research, it is very important to know the precise time of a crash, because all data analyses will rely on very microscopic values of traffic parameters prior to crashes. As a result, if there is a divergence between the real time of a crash and the reported time of a crash, then the statistical models will be unreliable. For that reason, in almost all relevant research in the field, a correction at the precise time of the crash is conducted before matching the crash and collecting the required traffic information, due to errors and inaccuracies of the crash time reported by the police.

The most effective way of correcting this is by conducting a thorough visual examination of the traffic time series prior to a crash and then by subtracting a few minutes such as, 1–5 min (time lag), from the reported time of the crash to adjust it. However, larger time lags are also possible, if strong crash time inaccuracies are expected.

This correction is carried out in order to avoid the impact of the crash on the traffic itself, for example, traffic jam. More specifically, when a crash occurs on a freeway, a traffic jam is highly likely to occur near the crash location and consequently traffic speeds are facing a sudden drop. Therefore, the researcher can spot the precise moment of the crash and correct the reported crash time, which is provided by police authorities.

Safety Indicators

Real-time Crash Risk

The concept of crash likelihood or real-time crash risk evaluation has been introduced in the last decade or more. Under this approach, a sample of “non-crash” cases (i.e., time periods when no crash occurred) is selected together with the traditional crash cases. Usually a matched-case control method is applied, where a sample of non-crash cases are matched to crashes that occurred at the same location, day of week, and time of day but at different time periods. The advantage is that by using this particular method, researchers are able to isolate the impact of traffic flow related variables on real-time crash risk, while at the same time be able to control for the road segment geometry and other factors.

Determining the crash/non-crash ratio is not simple. For instance, if a crash occurred at a specific point of a freeway, then a typical approach could be to gather traffic data at the same point, same time of day, one week before, and one week after. In this example, there will be two controls; non-crash cases and one crash case. Other crash-non-crash ratios could range from 1:4 to 1:10. However, a problem is that the actual number of non-crash cases are many more and crashes could be considered as “rare events”. Although being time consuming and costly, researchers could gather all non-crash cases from a freeway (i.e., all time slices in all road segments). In any case, the researcher could choose any crash-non-crash ratio and modify the analysis methodology accordingly, since the selected data collection strategies may affect model development. A remark is that, crash risk cannot only be expressed as crash-non-crash (0 = non-crash, 1 = crash), but also be crash with severity/no-crash or crash with type/no-crash.

Regarding the methods of analysis, various different methods have been employed. Because of the fact that the dependent variable is binary, it would be expected that binary logistic regression based models were frequently utilized (fixed or random effects). After the construction of the well-known utility function, the respective crash risk probability (or crash likelihood) for any specific set of parameters can be estimated. Bayesian models are flexible and can handle problems with multiple configurations; it is noted that Bayesian inference is one of the most applied approaches to date.

Moreover, other types of the binary logistic model include the conditional logistic model, the sequential logistic model etc. Recently, the advances in computational methods stimulated a large part of research to utilize data mining, machine learning (ML), Bayesian networks as well as neural networks. Traffic time series classification is also an option that has not been extensively explored. By that method, ML classifiers are tested on the original raw time series data, which are not further aggregated (Theofilatos et al., 2018).

Since it is often pursued to explore the impact traffic flow for classification purposes, modeling estimation includes also goodness of fit measures such as, overall accuracy, recall, specificity, and area under curve (AUC). In order to calculate sensitivity and specificity one needs to estimate:

- True positive rate (correctly classified crash case as a crash case)
- True negative rate (correctly classified non-crash case as a non-crash case)
- False positive rate (a non-crash case incorrectly classified as a crash case)
- False negative rate (a crash case incorrectly classified as a non-crash case)

Then the classification performance metrics can be estimated as:

$$\text{Overall accuracy} = \frac{\text{True positive} + \text{True negative}}{\text{Total crashes}} \quad (1)$$

$$\text{Recall} = \frac{\text{True positive}}{\text{True positive} + \text{False negative}} \quad (2)$$

$$\text{Specificity} = \frac{\text{True negative}}{\text{True negative} + \text{False positive}} \quad (3)$$

Another well-known classification performance is the AUC value of the receiver operating characteristic (ROC) curve. Akaike information criterion (AIC) values, deviance information criterion for Bayesian models (DIC) and pseudo-R squares could be used when performing model comparisons.

Lastly, some general trends regarding the traffic risk factors per se, it is observed that usually higher traffic volumes lead to higher crash likelihood, however, the results are not always consistent. On the other hand, high variations in traffic temporal or spatial aspects are often strongly correlated with higher crash risk.

Crash Frequency (Data and Methods)

AADT and Crash Frequency

Crash numbers are positive integers; therefore Poisson or negative binomial regression models are the main statistical models that are employed. It is often meaningful to normalize crash numbers per road segment length, per unit of time, or more advanced parameters of exposure, such as vehicle-kilometers. This is achieved by dividing crash numbers by the respective unit, thus transitioning to crash rates, which are positive real numbers. When the impact of AADT on crash rates is examined, simple linear regression models or censored regression models can be applied. It should be noted that in both cases considerably more advanced statistical methodologies have been developed, which are beyond the scope of this chapter.

AADT has also been employed in a spatial analysis context. Spatial correlation, indicating that neighboring areas have correlated crash counts, has been discovered for intersections along a given corridor due to similar patterns in traffic flow. Spatial analyses have shown that higher AADTs directly contribute to increased crash rate, measured as crashes per million entering vehicles. But, the crash rate for intersections depends more on what percentage of traffic is carried by the minor road than on the total entering volume. So, if we have, say, 10% of traffic on the minor road and 90% on the major road, increasing the flows gives a higher crash rate. For example, a Swedish model based on its entire state-road network shows that doubling the total entering volume at a non-signalized T-intersection from 10,000 to 20,000 vehicles per day (vpd) increases the crash rate by about 37% if we keep the percentage of traffic on the minor road at 10%. But if we instead add most of the “new” traffic to the minor road, so that they have close to equal traffic volumes and still an entering volume of 20,000 vpd, the crash rate is increased by over 200%. And, even lowering the total entering volume to 5,000 vpd with a 50/50 split (having 2,500 vpd on each road) gives a 64% higher crash rate than the double entering volume with 9,000 vpd on the major road and 1,000 vpd on the minor road. Traffic flows have been used in spatial studies extensively as exposure parameters in order to establish a common basis for crash risk comparison.

Real-time Traffic and Crash Frequency

A major difference between real-time crash risk and frequency models is that the latter are more aggregate. More specifically, when analyzing crash frequency with real-time traffic data, the road network should be divided in road segments in order to analyze the impact on the number of crashes per segment for a given time period (day, month, etc.). Aside from the flow variables discussed earlier, traffic volume can also be multiplied by the segment length in order to express a proxy of exposure.

Overall, a few issues arise in crash frequency analyses utilizing real-time data. First, when a road segment has experienced zero crashes, it is not clear which values of traffic flow should be used. One solution could be to rely on an even more aggregate but representative variable, such as a sensible average value of traffic flow (e.g., seasonal, average flow of the adjacent segments, etc.). Another solution is to use different road segmentation. Also, when zero crashes have occurred, it is still obvious that the expected number of crashes for that segment and that time period is greater than zero, even if only by a small fraction of one crash. When we predict crash numbers for a segment, we can give estimates with several decimals, but when we construct our models, we cannot easily determine the expected number of crashes for a segment with zero crashes recorded.

Another remark is the application of a robust methodology, when there are segments with more than one crash. In this case, the researcher has to take the mean value of the traffic variables from different time periods. The problem with this issue is that much information is lost and the estimates of traffic flow might not be reliable. Consequently, the use of disaggregate data in such cases does not have the expected benefits. To the best of our knowledge, this issue has yet to be solved.

Another issue is unobserved heterogeneity, as the impact of traffic flow may vary among road segments, thus not being fixed. For that reason, the models that are preferred are hierarchical or random effects models. It is noted, that the problem of excessive

zeros (i.e., a large number of segments with no reported crashes) can be solved by applying zero-inflated Poisson or negative binomial models.

In general, increased flow values are found to be associated with an increased number of crashes, but at a more aggregate level (i.e., daily counts). Please note that traffic occupancy (the fraction of time during which a detector embedded in the roadway is occupied) or degree of saturation values have been found to have the same effect and as such, the same (indirect) effect of real-time traffic flow can be considered due to the correlation of flow and occupancy. Overall, this topic needs further research as there is a lot of open issues that need to be tackled.

Crash Severity

AADT and Crash Severity

Crash injury severity is a parameter which requires a higher degree of data collection (number of injured people and separate degrees of injuries), which may also exceed some of the aforementioned data collection processes since the consideration of single vehicles is often not enough (for instance pedestrian casualties). Separate data collection methods are required instead, that can involve third parties (hospitals, insurance companies etc.). This reality, combined with the (fortunately) low overall numbers of crashes, results in crash injury severity being not as investigated as crash frequency.

When injury severity is considered, usually an approach of binary nature is adopted, depending on whether property damage only (PDO) crashes are recorded as well: For instance, 1 is assigned to crashes with injuries or fatalities, while 0 to PDO crashes. Alternatively, if PDO crashes are not recorded, researchers can examine mortality: 1 is assigned to crashes with severe injuries or fatalities while 0 to non-severe crashes. Finally, there are studies dedicated to injury severity that exploit rich and detailed datasets and employ methods like multinomial logit models in order to determine the characteristics of parameters leading to the crash. In all the aforementioned cases, AADT or ADT is used either as an exposure parameter or as one of the explanatory independent variables.

Real-time Traffic and Crash Severity

The impact of real-time traffic flow parameters on crash severity has received less attention than crash risk. This could be attributed to the fact that real-time safety evaluation has more focus on preventing a crash from occurring, rather than explore how a severe a crash could be. Similar to previous studies in the field examining the impact of AADT on crash severity, severity of a crash is mainly binary in nature, namely severe/fatal versus non-severe, such as in [Christoforou et al. \(2010\)](#).

A similar issue arising when studying crash severity with real-time traffic data is the potential unobserved heterogeneity. Hierarchical models (i.e., with random effects) or other models (i.e., latent class models) which address this issue could be established on the basis of either segment level or crash individual level, because these are the two main sources of heterogeneity. These models allow a number of variables to vary across different roadway segments or crash observations and in this way they account for the unobserved effects (roadway characteristics, environmental factors, and driver behavior). Other models should be used when the correct prediction is sought, for example, machine learning models, such as support vector machines. The problem is that machine-learning models are basically black box methods with limited interpretability of results; therefore a sensitivity analysis is needed as well to complement the analysis.

Regarding some core findings so far, it could be suggested that congested traffic leads to less severe crashes because of the lower driving speeds, but variations in traffic flow increase the crash severity, especially when being close to but just below congestion when traffic alternates between high speeds and almost stand still. Overall, research on the influence of real-time traffic on crash severity is relatively limited and more future studies should focus on this topic.

Conclusions

Research regarding the impact of traffic flow on road safety analysis is of critical importance and is gaining increasing attention. In the era of big data, social media, and other technological advances, there is still a lot of room for further research. For instance, if black boxes are installed in all vehicles, information on the trajectories, speeds, headways, and maneuvers of all vehicles could be acquired and analyzed. The exploitation of the large amounts of data through appropriate advanced real-time analyses could result in highly effective pro-active traffic safety management systems with great potential for safety improvement. Additionally, there is still research needed regarding the impact of traffic flow on motorcyclist safety. Lastly, the upcoming era of connected and autonomous vehicles (CAVs) could bring radical changes to our knowledge of the impact of traffic characteristics on road safety and more research in that direction is needed.

Background

Taxis play a significant role in the public transit system all over the world. In New York City, where the private car ownership rate is relatively low, the taxi service has a high utilization. In Europe, although private car ownership is relatively high, the taxi industry still employs more than 1 million people, accounting for 8% of transport employment (Bidasca and Townsend, 2016). With the rapid development of the sharing economy and the advent of mobile payment, ride-hailing service becomes a new choice of travelers. The ride-hailing service is characterized by the network information transmission and application ability and is different from the traditional taxi service. Globally, ride-hailing companies, such as Uber, Lyft, Ola, and DiDi, have jointly built a huge mobile travel network that serves more than 80% of the world's population and covers more than 1000 cities. In the context of traditional taxis and emerging ride-hailing service, traffic safety and security of these two modes become a vital issue that cannot be ignored. The objective of this study is to analyze and summarize the traffic safety and security of taxi and ride-hailing vehicles. We focus on the major risks and accident factors faced by taxi drivers and ride-hailing vehicle companies and provide suggestions for taxi and ride-hailing vehicle drivers as well as passengers to reduce risks.

Features

Comparison of Taxi Drivers, Ride-Hailing Vehicle Drivers, and Private Car Drivers

Taxi and ride-hailing drivers are more likely to be involved in accidents and accident-related injuries due to their occupational exposure to hazardous road conditions and particular activities, such as seeking locations, spotting potential passengers, and stopping to pick up or drop off passengers (Baker et al., 1976; Johnson et al., 1999; Chin and Huang, 2009). There are some factors that will influence driver behavior in taxi operations compared with private drivers, such as drivers, vehicles, roads, and so on (Chin and Huang, 2009). The corresponding factors and related reasons will be detailed introduced in the following text. The nature of the job is shift work, and the process includes cruising the streets, waiting at a fixed point, and a mix of both (Tseng, 2013).

Comparison of Ride-Hailing Vehicle Drivers and Taxi Drivers

Ride-hailing drivers may be less familiar with the road network compared with taxi drivers and they usually drive with navigation. While driving, drivers will check their mobile phones or car navigation screens from time to time, which may lead to potential safety risks. Besides, ride-hailing drivers have additional mobile phone operations, because customers request vehicles through their smartphones and ride-hailing drivers need to contact with the passenger and locate the passenger.

Taxi companies regularly or irregularly train taxi drivers on policies and regulations, etiquette, professional ethics, foreign languages, and other aspects. Traffic police and other departments also train taxi company managers and drivers in relevant aspects. In some countries, like Sweden, a driver needs a special national license to drive a taxi, which includes passing criminal background checks, medical tests, theoretical tests, and driving tests that go far beyond the standard testing for driving a passenger vehicle. Before March 2018, ride-hailing drivers in Sweden only needed a regular driver's license but, since that time, these drivers are also required to have the special taxi license. The management of ride-hailing vehicle drivers is relatively simple. The professional ability of ride-hailing drivers may in many countries be insufficient, and moral quality is uneven. The security problem of ride-hailing vehicles is also very prominent.

Facts

The traffic accident statistics in Shenzhen city in 2017 show that a total of 3879 crashes occurred that involved ride-hailing vehicles. In terms of the proportion of the number of vehicles involved and the total number of platform registrations, the proportion of ride-hailing vehicle accident accounts for 7.15% of all reported accidents, while the taxi traffic accident proportion is 1.78%. Private car accident accounts for 0.28%. The difference in traffic accident rates among traditional taxis, ride-hailing vehicles, and private cars is mainly related to the amount of travel mileage. In the same period, the liability rate of traffic accidents for taxis was 55.6%, very similar to the 54.5% of ride-hailing vehicle drivers being deemed at fault.

China judicial big data service platform has released a list of crimes committed during online ride-hailing and traditional taxi services in 2017. The incidence rate of 10,000 traditional taxi drivers is 0.627, while that of ride-hailing drivers is 0.048. In the process of providing services, the nighttime is the peak time for a crime. About 50% of the cases for ride-hailing drivers and nearly 30% of the cases for traditional taxis take place in this period. As reported by CNN on January 21, 2019, Uber has 1200 incidents reported every week. This includes rapes, other sexual assaults, serious traffic accidents, and even deaths. They also speculated that many incidents are not reported so the true numbers may be even higher even if some of the included reports are false reports.

Taxi and Ride-Hailing Vehicle Accidents Analysis of Factors

Since very few studies have been conducted specifically for the safety of ride-hailing vehicles, this paper majorly summarizes the accident factors obtained for generalized taxis, which may also be useful for understanding the ride-hailing vehicles given their similar operational features.

Drivers

Drivers of taxi and ride-share vehicles can be assumed to behave similarly to drivers of other vehicles. However, it is possible that drivers of these vehicles differ with respect to age, gender, or personality type. In some countries, it may be possible to get a ride-sharing job even if you have a personality type that makes it difficult to hold employment in many other sectors. The average education level may also differ.

Age

As an important risk group in traffic, the contribution of young drivers to motor vehicle deaths is confirmed to be disproportionate. The number of fatal crashes per 100,000 licensed drivers between the ages of 15 and 24 is much higher than those from 25 to 45-year-old people (Karpf and Williams, 1983). Young drivers drive more recklessly compared with older drivers. Besides, young drivers have less ability to perceive the environmental risks involved in the operations of motor vehicles compared with more experienced drivers

(Matthews and Moran, 1986; Finn and Bragg, 1986). Thus, youth participation in motor vehicle accidents in the United States and around the world has long been considered a major public health problem.

Moreover, there are, at least in Singapore, 50- to 59-year-old and above 59-year-old drivers who have a higher probability of being involved in accidents than those in their 40s. Causes have been found for the 50- to 59-year-old group and above 59-year-old group, respectively. The common cause is failing to give way. Drivers who are above 59 years old have a little bit more risks than those aged 50–59 because of causes including changing lanes without due care, failing to have proper control, and turning without due care. It is clear that the older group has more difficulties in making good judgments associated with traffic conditions, even though older people have more propensity to obey traffic rules. Failing to give way is another common problem among older drivers, which shows that older people have reduced capability in judging road rights. The most significant cause for above 59-year-old drivers having crashes is changing lanes without due care, which may be associated with a retrogressive ability to judge gaps in traffic streams. For the more senior group, failing to have proper control and turning without due care are also significant, suggesting that the ability to interact with other vehicles may also deteriorate with age when an interaction is required. These problems could be because the elderly have worse issues with physical, perception, and reaction capabilities derived from declining eyesight, weaker muscle strength, and reduced alertness.

However, in the United States, where elderly drivers have been driving since they were young, the driver fatality rate per mile driven stay at a low level and constant for age groups from 30 to 64 and then increase slowly for people up to 70, and by age 75 reach the same level as that of 20–24-year olds, and by age 80–85 is roughly as high as for teenage drivers.

Gender

Studies in some countries have shown that female taxi drivers have a higher risk of accident-related mortality and injury than male taxi drivers. This result accords with the data reported in a study in Australia that the rate of hospitalization of female car drivers is higher than that of men (Lam, 2004). This may be because accidents involving female drivers are more frequently caused by panic, especially for novice female drivers. On the other hand, male drivers are more prone to road rage and aggressive driving. And, overall, US data indicate that women on average are much safer drivers than men. FARS database for 2015 shows that there were 32,082 fatal crashes in the United States involving 48,613 vehicles. Those vehicles had male drivers in 35,472 cases and female drivers in 12,220 cases and unknown or unreported gender (or no driver) in 921 cases. This gives a male to female ratio of 2.90 (or 74.3% males and 25.7% women out of known gender). The Federal Highway Administration (FHWA) stated in July 2016 that the average miles driven by male drivers were 16,550 miles per year and by female drivers 10,142 miles per year. If we had equal number of male and female drivers, that would mean that 62.0% of all miles were driven by men and 38.0% by women. But the numbers of male and female drivers in the United States are not identical. Since 2005, there are slightly more female drivers and therefore the percent of all miles driven by men in 2015 was slightly below 62.0%, or about 61.8%. So men should be the driver in 61.8% of all fatal crashes if they were equally safe, but men were involved in 74.3%, so men are 20.2% worse than the average driver $[(74.3 - 61.8)/61.8 = 0.202]$. Women should be the driver in 38.2% but are involved in only 25.7%, meaning they are 32.7% safer than the average driver. This means that if the average driver was involved in 100 fatal crashes, male drivers, driving average distance, would be involved in 120.2 and female drivers would be involved in 67.3. In other words, men have 78.6% more fatal crashes than women per mile driven.

Fatigue

Driving for more than 8 h a day significantly reduces the response time of drivers. This finding is supported by a study showing that more than 2 million crashes in the United States in 2008 were attributed to driver fatigue.

In accident causal investigations, taxi drivers do not usually attribute accidents to fatigue, because the drivers may not realize they are tired, or if they realize it, they may not admit it (Corfittsen, 1993). If there is no emergency during the driving, a driver could drive without incidents. However, once there is an emergency, a driver may react too slowly to avoid the accident because of fatigue or sleepiness. Drivers may attribute accidents to the emergency instead of fatigue. Thus, fatigue is a potential boost to accidents through slow operations and awareness of danger. Fatigue generally comes from lack of sleep and circadian rhythm disruption (Dalziel and Job, 1997). For taxi drivers and ride-hailing drivers, picking up passengers is a career to make a living. Taxi drivers and ride-hailing drivers may choose to reduce the rest time as much as possible and constantly look for potential passengers. Moreover, taxi drivers may work in shifts. For those who do not work in regular shifts, the fatigue caused by the chaotic biological clock is a big safety risk. In many countries, ride-hailing services do not have limits to the hours a driver can work and even in a country like Sweden, a driver can operate up to 13 h per 24-h period, since the rest period needs to be only 11 h per day. Furthermore, not all vehicles are equipped with electronic logging that shows who has been operating a specific vehicle.

Income

US studies show that there is a strong relationship between a driver's crash rate and income. At least one study shows that the higher the driver's income, the lower the crash rate. Also, when the United States hit a deep recession in 2009, which lowered the incomes of taxi drivers, their crash rates significantly increased.

Speed and Speeding Violation

Literature shows that speed is an important factor in road safety and has a direct causal relationship with traffic accidents. The risk of a fatal crash is roughly proportional to speed to the power of four, meaning that if speed is doubled, the expected risk of a fatal crashes increases by a factor of 16. And, taxi and ride-share drivers may speed more than other drivers. One main harm of driving at higher

speed is that the line of sight becomes narrower and the definition decreases. When traveling faster, the braking distance also becomes longer. When speeding, people's psychology may also be stressed, since they fear being caught by police, especially under complex road conditions, in which drivers may panic and make operational errors. As for taxi drivers, it has been confirmed that they commit speeding violations associated with operating styles, working time, work experience, daily driving distance, and sensation-seeking personality (Tseng, 2013). Novice taxi drivers are more likely to commit speeding violations than senior taxi drivers because of insufficient knowledge of local geography and unfamiliarity with the roads and traffic conditions. Drivers who cruise the streets are less likely to commit speeding violations than drivers on route to pick up or deliver passengers. Taxi drivers cruising down a street often need to find a fare for the next ride and have more opportunities to turn around or stop suddenly to pick up passengers so they might drive at a slower speed but may also brake or turn suddenly. However, drivers waiting at fixed points usually take passengers directly to their destinations, and they may drive faster to shorten the travel time and increase the frequency of workload. People who drive late at night have a higher chance to commit speeding violations than those who drive at other times. One possible reason is that the traffic situation at night often is less congested than that during the day, so that drivers may drive at higher speeds. Besides, the more daily driving miles, the more speeding violations. This conclusion is following that driving mileage is the most important predictor of driver violations and accident involvement. Moreover, it has been suggested that people with sensation-seeking personalities are more inclined to have speeding violations, and they may also be more likely to be taxi drivers than people with other personality types (Burns and Wilde, 1995).

Vehicle

Vehicle Condition

In the United States and Europe, having a vehicle factor being the main contributor to a crash occurs in less than 3% of crashes, but vehicle factors contribute to approximately 13% of all crashes. Problems of vehicles, especially in poorer countries, often include lighting problems, brake failure, and a flat tire, among which the most important factor is the problem of tire failure, which is also the main cause of high-speed traffic accidents in China. The cause of flat tires is generally that the owners pay little attention to maintenance, including high or insufficient air pressure, and tires being severely worn. This may be more common for taxis than other vehicles since the owner often is not the operator. Road conditions and excessive and severe tire temperatures are potential dangers causing flat tires. And, the tire may get punctured by sharp objects, followed by air leakage which causes a flat tire. Also, if the ambient temperature is too high, or driving at higher speeds than the tire is rated for over long time periods, can make the tire temperature too high, and may cause the tire to burst, thus prone to traffic accidents. Besides that, the taxi may not necessarily be a taxi driver's car, where they do not pay attention to the maintenance of the car, taxis, and ride-hailing vehicles are driven longer distances than most vehicles. Hence, the vehicle condition may degrade quicker, meaning that annual safety inspections—which are not even mandatory in all jurisdictions—are not enough to maintain the vehicle in a safe condition, which may be extra important for taxi and ride-hailing drivers.

Vehicle Color

Studies show that yellow taxis have fewer accidents per month than blue taxis (Ho et al., 2017). The reason is that yellow taxis are more visible than blue ones, especially in front of another car. Other drivers are therefore better able to avoid hitting them, especially at night, and the accident rate is therefore reduced. Also, when driving in rain or fog, drivers have a worse vision, and the vehicle color may play a vital role in sideswipe and rear-end crashes. For head-on collisions, vehicle color has very little effect since little of the frontal area is painted and operating with daytime running lights is a much more important factor in being visible to others (Ho et al., 2017).

Road

Road Section

Per distance driven, intersections constitute a higher risk than other road sections. And, there is a higher probability of taxi drivers being involved in accidents when driving through intersections than elsewhere. At intersections, drivers need to adjust speed due to the signal controls or other junction controls. Besides, it is indicated that taxi drivers have higher risks at intersections compared with general car drivers. Taxi operations with an increased workload are responsible for the higher risk. The additional workload includes picking up or dropping off passengers near intersections as well as unfamiliarity of route and traffic conditions. Significant causes of accidents at intersections are disobeying traffic signs and signals, failing to give way, and turning without due care. These three causes may be because of reckless or careless driver actions resulting from high workload as mentioned earlier or from these drivers being more aggressive than drivers in general.

Roadway Type

As for taxis, like other drivers, limited-access highways (expressways) are safer than other roadway types. Taxi drivers have a higher risk of being responsible for accidents on non-expressway than the expressway. The reasons for the relatively high tendency are as follows: failing to give way, disobeying traffic signs and signals, and turning without due care. In non-expressway conditions, taxi drivers have more pressure resulting from the requirement to stop for boarding and alighting, look for potential passengers, and make quick decisions to navigate. In the process, taxi drivers may be at fault derived from indiscriminate lane changing, turning,

stopping, and possible lack of concentration. Besides, taxi drivers may have little awareness of street and traffic conditions. Taxi drivers' errors of judgment and actions affected by these possible factors will increase the risk of accidents.

Road Surface

Wet road surfaces make driving riskier. Taxi drivers being at fault have a higher risk on wet road surfaces compared with dry road surfaces. Two causes that have been found to have a higher propensity are failing to keep a proper lookout and failing to have proper control. When driving on wet roads, it is easy to slip, and driving in the rain, fog, and snow will be affected by not only wet roads but also reduced visibility, increasing the workload and driving tension of taxi drivers and ride-hailing vehicle drivers. Taxi and ride-hailing vehicle drivers, by nature of their profession, are subject to longer periods of stress in rainy conditions and bad visibility, which may reduce performance level and increase the likelihood of incorrect judgments. Under this circumstance, taxi driving will be more hazardous.

Horizontal Element

Taxi drivers have a higher risk on straight roads than in horizontal curves, compared with private car drivers. This factor is significant because of the way taxi drivers operate. There is a clear distinction between taxi drivers and private drivers driving on straight roads. More passenger-related activities exist on straight roads, including stopping for boarding and alighting for passengers. Because of this demand for more stops of taxi drivers while private car drivers do not have to do, and the longer period of stopping at the request of passengers, potential risks in the process of waiting make taxi driving more hazardous.

Travel Time

Day of Week

Taxi driving on weekdays has a higher probability to involve accidents than on weekends. Compared with ordinary car drivers, taxi drivers are more likely to get involved in accidents when driving on weekdays. Several causes are responsible for the higher risk. Driving during workdays is more stressful because the traffic is heavier and tends to be concentrated during peak periods due to commuting and the driver workload is higher due to increased interaction with traffic in a variety of operations. Besides, in modern cities such as Singapore, there are traffic controls that are only implemented on weekdays, such as an exclusive bus lane system and the Electronic Road Pricing (ERP) system, which increase the workload of drivers' in-vehicle control and navigation and make driving more dangerous. Thus, when taxi drivers drive on a weekday, a higher level of mental alertness is needed and this affects driving abilities.

Time of Day

Studies have found that nighttime driving has higher risks compared with other driving time for all drivers. Taxi drivers' nighttime driving has an even higher chance of involvement in accidents than daytime driving (Corfitsen, 1993). Although there are fewer pedestrians and lower traffic flow at night than during the day, visibility at night decreases, which negatively affects reading traffic signs and interpreting the street environment. Furthermore, travel speeds may increase during nighttime. And it has been suggested that poor vision and visual problems are associated with an increased risk of motor vehicle accidents among many taxi drivers.

Moreover, compared with general car drivers, taxi drivers have a higher probability to be involved in accidents when driving at night than in the day. Because of the nature of taxi drivers' work, they may need to drive in unfamiliar areas, and they may not be proficient in local geography and traffic conditions. Besides, taxi drivers still have the greater need to seek locations, spot potential passengers, stop for boarding and alighting under poorer night-vision conditions, and taxi drivers may suffer from fatigue. It appears that more attention should be paid to night driving, especially for taxi drivers' nighttime driving which has a considerable risk to drivers as well as passengers.

Vehicle Occupancy

The risk is increased by over 20% for taxi drivers who are not carrying any passengers. It is reasonable that taxi drivers will be more cautious when taking passengers (Lam, 2004). Once passengers are injured in a taxi, taxi drivers may have financial liability. Furthermore, taxi drivers need to pick up passengers, and when there are no passengers in cars, they will try their best to find possible passengers or answer the phone for a reservation. To maximize the passenger-carriage time, taxi drivers may rush to the waiting passengers for picking up. Under such circumstances, reckless driving behaviors may happen, such as speeding, changing lanes without due care, and turning without due care, and hence increase the chance of accidents.

Safety Belt Use

Safety belt use has been shown to reduce motor vehicle fatalities by about 45% and serious injuries by more than 50% (Fielding et al., 2001). However, there is in many jurisdictions an exemption for taxi drivers that they do not need to wear seat belts because of the need to frequently enter and exit a vehicle. The ratio of taxi drivers' seat-belt use in Boston is less than 10%, significantly lower than other drivers in Massachusetts (Fernandez, 2005). The safety impact of not using seat belts is very serious, so seat-belt legislation should be strengthened. Even in Sweden, which has mandated seat-belt use in taxis since 1999, it is still permitted that children travel short distances at low speed in the back seat without proper child seats. But seat-belt use in taxis in Sweden has been above 90% since

2006 and reached 96% in the latest comprehensive state-organized observation study in 2013, which included over 1200 taxis. That is almost as high a usage rate as in other passenger vehicles.

Even with safety restraints, taxi passengers have higher injury rates compared to car occupants. Experts believe that this trend is linked to the presence of partition in most taxis.

Speed Limit

The speed limit has been identified as a significant factor in risk. Many countries use 40 km/h, 70 km/h, and 90 km/h as standard speed limits and they are confirmed to be significant among categories of speed limits. On low-speed roads with a 40 km/h limit, taxi drivers have a higher risk of involvement in accidents than on 50 km/h streets in the empirical studies conducted in Singapore. The causes are failing to give way, changing lanes without due care, and turning without due care. The reason for accidents on the low-speed road is associated with passenger-related activities, including seeking for potential passengers and stopping and waiting for picking up or dropping off passengers. In this case, the taxi drivers have to undertake more searches and navigation workload. Besides, taxi drivers may have some reckless behaviors due to unfamiliarity with the road environment and the low-speed roads. It could be suggested that the speed limit on urban local streets should be lowered from 40 to 30 km/h, as in much of Europe, or even to 20 or 10 km/h as is the case in most of downtown Berlin since 2017.

The 70 km/h roads are typically semi-expressway routes, and taxi drivers are more likely to be involved in accidents there too. Driver errors are associated with navigation and other distracted attention at high speed rather than passenger activities. The causes of accidents are failing to have proper control and following a car too closely. It is more associated with driver behaviors than taxi operations. At a 90-km/h speed limit, there is an increased probability of accident responsibility when compared with the reference category. Several other causes are dominant on the expressway. These are failing to keep a proper lookout, changing lanes without due care, and failing to have proper control. Contrary to earlier findings, the expressway is less risky than other roads. The finding could be related to some high-risk behaviors by taxi drivers, such as speeding, which could indicate that taxi drivers are more likely to make mistakes in such situations. Although expressways are safer environments than urban streets, it suggests that expressway driving still has certain risk associations. Since the speed limit is not one of the important factors related to taxi operation, these specific expressway driving risks are related to poor driver behaviors.

Collision Type

Taxi drivers are nearly twice as likely to be involved in multi-vehicle collisions as in single-vehicle collisions when compared with general car drivers. This factor is related to taxi operations rather than drivers themselves. The significant causes include failing to give way and changing lanes without proper care. It may be because of drivers' making errors of judgment or action when responding to passenger calls rather than poor driving skills.

Recommendations

Safer Drivers

- ETSCs PRAISE (Preventing Road Accidents and Injuries for the Safety of Employees) project provides some corresponding countermeasures about how to make taxis safer ([Bidasca and Townsend, 2016](#)).
- Mandatory driving training programs and education and information need to be developed to ensure that taxi drivers are better prepared to conduct their business with considerations of the safety of passengers and other road users. Ride-share drivers should be mandated to have the same licensing requirements as taxi drivers if they pick up passengers for a fee.
- Countermeasures need to be taken to prevent fatigue among taxi drivers. This can be achieved through legislation to limit working hours and mandating electronic log systems where drivers use their personal state-issued taxi certificate to ensure that drivers do not drive extra hours for more than one company, or drive under two identities. Education, information, and training will be needed to get acceptance for this and other measures.
- Taxi drivers and all passengers including children should be required to wear seat belts or be seated in child seats/on fixed cushions if shorter than 135 cm, with no exception for short trips.
- Strengthen the law enforcement of drunk driving for improving the safety of services.
- Taxi companies formulate reasonable safety management policies to ensure that shift patterns, travel plans, employment contracts, and work schedules do not create time management stress for employees, leading to driver fatigue and stress.
- The ride-hailing vehicle platform and management department need to strengthen the function of reviewing and ensuring the safety of ride-hailing vehicle drivers and include the ride-hailing service into the taxi-service assessment system.

Safer Vehicles

- Develop vehicle management policies and procedures.
- The taxi vehicle safety technical requirements, including vehicle occupant protection, vehicle safety technical equipment, etc., shall be formulated strictly following the legal requirements.

- Those responsible for the procurement of taxis within the organization should communicate closely with the safety department and relevant supervisors and management.
- Taxi companies communicate vehicle safety technology to their employees to keep them safer and train them to use the equipment properly.
- Maintenance personnel shall periodically assess the appropriate high standards and ensure that approved replacement parts are used in the vehicle, particularly for safety-critical components such as brakes and tires.

Ensure the Safety of Passengers

- Draw up a list to be noticed and advertised when booking and entering a taxi.
- To equip taxis with child safety restraints where practicable.
- Allow passengers to provide meaningful feedback to drivers on key risk factors (speed, seat belts, pickup locations, etc.).
- Taxi drivers carrying designated vehicles for people with mobility problems should be trained and equipped with wheelchairs at no additional charge.
- Taxi passengers themselves can take measures to ensure their risks are minimized. When using the services of the taxi or the ride-hailing platform, passengers should have appropriate safety awareness.
- Passengers are often embarrassed to tell drivers to slow down. And, some passengers even egg on drivers because they like traveling fast or are short on time to get to airports, etc. Therefore, within a reasonable number of years, all taxis should be equipped with speed governors that use GPS or automatic sign reading, making it impossible for drivers to exceed the speed limit by even 1 km/h except for very short distances, similar to what is proposed to be an EU rule for all motor vehicles starting with new models from May 2022 on. In taxis, such systems should be retrofitted into older models too at a later date.

Introduction

Traffic signals are installed at road intersections to improve their capacity or safety or both. Conditions for which traffic signals are justified as potentially beneficial are known as traffic signal warrants. In the United States, there are currently nine signal warrants, four of them relate to vehicle and pedestrian traffic volume, and another four consider signal coordination, road network, and the presence of schools and railway crossings. The remaining safety-focused warrant allows signalization if:

- other means of safety improvement are exhausted;
- at least five police-reportable crashes susceptible to correction by traffic signal control occurred within a 12-month period; and
- the threshold of at least one traffic volume warrant is met by at least 80%.

It is apparent that the use of traffic signals as a means of safety improvement is warranted only under quite restrictive conditions.

Traffic signals allow certain movements across an intersection while holding other movements at a stop. Each of the alternating periods contains a set of allowed movements, and is called the signal phase (Fig. 1). In the United States, signals go from green to yellow to red and back to green. In many other countries, there is also a period showing red plus yellow simultaneously to indicate that the green light will soon be displayed. The signal's safety benefit is affected by the absence of serious conflicts among movements allowed in each phase and by separating consecutive phases with sufficiently long clearance periods. A clearance period consists of a yellow signal that warns about an upcoming red signal and an all-red period when no traffic from any direction may enter the intersection (Fig. 1). The yellow signal must be sufficiently long to avoid what is known as a dilemma zone, where an approaching driver cannot stop before the intersection and cannot enter the intersection before the yellow signal turns red. Fig. 2 presents this zone as an overlap of two sections marked with gray bars: (1) the section where the vehicle is too far to reach the intersection during the yellow signal, and (2) the section where the vehicle is too close to stop before the intersection. Although traffic signals tend to reduce the number of right-angle collisions, traffic interruptions introduced by red signals expose vehicles to rear-end collisions. Yellow signals that are too short may cause both additional rear-end collisions due to rapid braking and right-angle collisions due to voluntary or unavoidable violations of red signals.

An intriguing dilemma zone control is being used in Sweden called LHOVRA. It uses a sequence of detectors placed along the approach to an intersection. The detectors determine vehicle type and speed and the change period is adjusted to minimize the dilemma zone occurrence. It may not be applied in countries where the signal standards require fixed yellow and all-red intervals.

Red Signal Violation

Drivers may violate red signals intentionally to avoid stopping and being delayed. Enforcement by police or red-light-running cameras may reduce both red signal violations and associated right-angle collisions. A flashing advance warning signal is installed at some intersections. Its flashing light and message, "Prepare to Stop When Flashing," reduces unintentional red-light running by

Figure 1 Signal phases and clearance periods.

Figure 2 Dilemma zone on an approach to a signalized intersection.

warning that a yellow signal is coming soon, and will be followed by a red signal. The device also helps protect against the dilemma zone and alerts motorists where the sight distance is limited.

Long red signals may cause uncertainty, among drivers already stopped and waiting, about the proper functioning of traffic signals, particularly if no traffic movements occur from other approaches. This uncertainty may lead to a driver entering the intersection before the red signal ends. Long red signals may also increase signal violation by regular users of the roadway, who may elect to move through the intersection on a yellow signal to avoid what they anticipate to be a long waiting time.

Queue Presence

Research indicates that rear-end collisions may be associated with long queues on arterial streets with signal coordination. Clearing a queue takes time during the green signal, and during that time stopped vehicles block lanes to groups of vehicles arriving from upstream intersections. The presence of stopped vehicles may be difficult for these approaching drivers to see if they are following other vehicles closely. Forced to brake rapidly, they cause the additional risk of rear-end collision with vehicles behind them. Signal coordination reduces the risk of rear-end collision if it schedules the arrival of upstream vehicles after queues are cleared at the intersection they are approaching.

Missing or short turning bays are another potential cause of rear-end collisions because vehicles waiting to turn block the through traffic with whom they share the lane. Although designing longer turning bays or extending existing bays are effective countermeasures, shortage of space or excessive costs may prohibit these solutions. Where capacity is not a problem and recorded collisions confirm a short turning bay problem, a viable solution may be to control queue length in the turning bay by recalling a green signal. The green signal is recalled if a detector placed at the end of the turning bay indicates the continuous presence of vehicles.

Pavement Friction

The ability to effectively brake is a fundamental condition of successfully avoiding a rear-end collision. Approaches to signalized intersections may experience drivers' frequent braking maneuvers that involve locking brakes, causing tires to slide on the pavement. Over time, the mineral seeds in the pavement, particularly bituminous pavement, are exposed and polished. The coefficient of friction can be quite low, which considerably reduces driver acceleration rate. Proper treatment of the damaged pavement increases the friction coefficient even above the original friction of new pavement.

Permissive Left Turns

Left-turn collisions occur between vehicles turning left and vehicles moving through from the opposite approach. These collisions can be eliminated or reduced by letting left-turn vehicles move while displaying red signal to through vehicles (the protected left

Figure 3 Permissive (or permitted) and protected left turns.

Figure 4 Flashing left arrow to emphasize that the left turn is permitted but not protected.

turns case in [Fig. 3](#)). This solution is not always applied, however, and instead, opposing traffic movements are presented with circular green signals simultaneously. In such cases, drivers turning left must wait for sufficiently long gaps in the oncoming traffic. The gray left-turn arrows in [Fig. 3](#) indicate this situation. Left-turn collisions are caused by drivers turning left who misperceive a gap in opposing traffic when road speed is high, sight distance of oncoming traffic obscured by vehicles moving in multiple lanes, and/or by a vertical curve on the opposite approach. These conditions, which are exacerbated when left-turning vehicles are permitted to turn left from two or more lanes, motivate protection of left-turn movements. An additional potential problem is drivers misunderstanding the green circular signal and assuming that they may safely turn left. An improvement related particularly to that misunderstanding warns drivers about permissive left turns by implementation of a flashing yellow left arrow presented when left-turning vehicles are not protected and must yield to the opposite through traffic ([Fig. 4](#)).

Restricting left-turn movements are considered when an intersection experiences an excessive frequency of left-turn collisions, or a shortage of capacity with its consequential risk of rear-end crashes. Restricting movement is viable as long as alternative routes for left-turning vehicles are available. A more expensive solution is to remove the left-turn through movement conflict from the intersection by adding signalized crossovers before an approach to the intersection that would permit travel on the opposite side of the road, and then divert it back to the original side once traffic has passed the intersection. Various forms of this solution include continuous flow intersections, signalized upstream crossovers, and diverging diamond interchanges ([Fig. 5](#)). The capacity benefits of such treatment have been confirmed, but the safety effect is uncertain. The addition of traffic signals at crossovers and potentially confusing movement paths are among the safety-related drawbacks.

Permissive Right Turn on Red

The permissive right turn on red (RTOR) signal was introduced in 1925 at signalized intersections in Los Angeles, California. In the 1970s, RTOR spread across the United States at signalized intersections, and then later to Canada, as a means of saving time and fuel. The maneuver was considered safe for its simplicity. After passing the crosswalk on approaching an intersection, a driver could proceed if there were no vehicle in the right-most lane of the intersecting road. The RTOR provision was common at signalized intersections until safety studies indicated a heightened risk of collision with pedestrians on the two crosswalks a driver had to pass. Motorists focused on vehicle traffic approaching on their left and did not pay sufficient attention to pedestrians on their right. In addition, attaining a position convenient for examining gaps on a major road before accepting them required the driver to pull forward, thus blocking the crosswalk on the current approach if the crosswalk did not offset a sufficient distance from the curb line. Research studies confirmed occurrence of collisions caused by the permissive RTOR.

Figure 5 Diverging diamond interchange.

Signal Design and Settings

Traffic signal design includes selecting type and sequence of signal phases and designing change periods. The length of the green signal must be determined in advance if the signal is to be controlled by clock. If signals are to be actuated by a signal controller, signal settings need to be decided. Additional design decisions include coordination with adjacent signals, in which more signal settings are added to establish a coordination plan. A coordination plan imposes constraints on local signal actuation to maintain smooth movements of vehicles along a sequence of coordinated signalized intersections.

Faulty signal design may affect safety at signalized intersections. Faulty design includes too short yellow signals, too long red signals, permissive left-turn phases in nonconductive conditions, and poor signal coordination that sends vehicles into the back of a queue still present at the downstream intersection. Poor coordination resulting in long queues and long waiting times may increase the violation of red signals and lead to additional collisions. A similar effect may result from premature termination of green signals by incorrect settings. The resultant phase failures force drivers to wait through another red signal, increasing their propensity to violate the signal. Another potential safety problem may be produced by inconsistent use of leading and lagging left-turn phases. In such cases, the through traffic on opposing approaches to an intersection does not receive green signals at the same time. Local drivers, who become accustomed to the order at which each approach receives a green signal, may become confused if that order is changed at different intersections in the same area, or even worse, at an intersection during different times of the day. Confused left-turning drivers may inadvertently violate the right way of through traffic from the opposite approach. Consistency in signal and geometric design of intersections increases drivers' expectancy, which promotes compliant behavior and enhanced performance.

New Signal Installations

New traffic signal installations should be supplemented with signs posting warnings about the new signals. Otherwise, local drivers may be surprised by the signals and the presence of stopped vehicles along their travel route. Where possible, stops signs should be installed on all approaches of the intersection in the period preceding traffic signals in order to prepare local drivers for the upcoming traffic interruption. Permanent warning signs may be warranted where the traffic signals' visibility is reduced by curves or other obstructions.

Signals Visibility and Readability

Drivers cannot follow traffic signals if these signals are not seen or not understood. The importance of clear and non-confusing signals for left-turning drivers in the United States has already been discussed. But, just crossing the border into Canada, drivers are faced with flashing green lights. In Canada this means the same as a green arrow, that they have an exclusive left turn. However, in many other countries, a flashing circular green signal means that the green will soon turn yellow. A general requirement for signals is their visibility and clarity to road users approaching an intersection. The first moment of importance is when the intersection first comes into view. Signal heads and their indications should be seen in advance to help road users notice the presence of traffic signals

and to approach the intersection in the proper lane. Information redundancy is important, and can be accomplished with properly aligned pavement edges and markings, road signs, and traffic signals. Enhancement of traffic signals' visibility and clarity is accomplished by placing the signals on the right-hand side and repeating them if needed on the left-hand side in medians, divisional islands, or elongated separators. The conditions that prompt repeating signals on the left-hand side include multiple lanes, the presence of tall vehicles in traffic, and the need to display different signals for different movements. An overhead position of signal heads is recommended under certain conditions, which include high speed, multiple lanes, the presence of tall vehicles in traffic, and lane-based traffic control.

Traffic signal visibility can be improved by (1) replacing 8-inch (200 mm) lenses with 12-inch (300 mm), (2) installing shades to eliminate direct sunlight on signal lenses, and/or (3) adding backplates with retroreflective borders. It should be obvious to approaching road users which signals apply to them. This communication is accomplished in most countries by (1) using turn signals (arrow silhouettes or cutoffs placed on circular lenses) to indicate the traffic movements being controlled by individual signal heads, (2) reserving solid round signal lenses for all turns including solid green for permissive left and right turns, (3) emphasizing the permissive left turn by adding a flashing left-turn signal to the round green signal, (4) reserving solid arrow signals for individual movements including protected left and right turns, (5) installing signal heads for individual lanes above the corresponding lanes, and (6) adding text or symbols for clarification, if needed.

Drivers seeing signals addressed to other road users may add confusion or uncertainty, so should be avoided. Reducing the visibility of signals addressed to others can be accomplished by (1) properly directing signal heads toward locations with drivers who are intended to see the signal, (2) using protruding shades (screens, covers, etc.) that hide the signal from certain angles, and (3) using polarized lenses that allow viewing the signal light only from a sufficiently close position. A separate precaution is proper maintenance of signal heads and trimming vegetation in their vicinity. Overgrown trees may partly or completely block the view of signal heads.

Pedestrians at Signalized Intersections

Pedestrians are present at most signalized intersections in urban areas. Pedestrians are vulnerable road users and their safety at signalized intersections must be carefully considered when designing and operating traffic signals. Due to the quite different character of vehicles and pedestrians, these two groups are treated differently. Pedestrian are not subject to formal instructions and training as drivers are, so their signals must be easy to interpret. Pedestrian *Walk* signals shaped as walking human silhouette and *Do not walk* signals shaped as upraised hand or standing silhouette convey a clear meaning and help distinguish them from vehicle signals. *Do not walk* signal flashes during the pedestrian change period and is solid in the vehicle phase. Unlike vehicles, pedestrians require neither considerable distance nor time to slow down and stop. For this reason, they do not require an additional signal, equivalent to the yellow signal for vehicles, to warn them about the shortly appearing *Do not walk* signal.

Similarly to vehicles, pedestrians require time to clear the roadway after their walk signal ends. The clearance time should allow pedestrians to cross the entire length of the crosswalk to an area where they are safely separated from moving vehicles. The time is determined by assuming a slightly higher walking speed than the recommended 4 ft/s (1.2 m/s) pedestrian speed for crosswalk design; this speed may be reduced where elderly, children, or strollers are expected at a higher rate than usual. Although recommended standards may allow a clearance time sufficient to bring pedestrians from a curb to a pedestrian refuge island, prudence encourages making this time long enough to let pedestrians walk completely to the other side of the roadway. Crossing a roadway in two phases is justified only if the dividing median is wide enough to discourage pedestrians from attempting to continue past the end of the walk signal.

Violation of the *Do not walk* signal, particularly first few seconds, by pedestrians is quite frequent. One method of reducing this behavior is displaying a countdown of time remaining to the end of the pedestrian change period when green signals for conflicting vehicles begin. Such information may discourage pedestrians from starting crossing too late to finish safely.

Where pedestrian safety is of concern, such as in downtown areas with high pedestrian traffic and on crosswalks of high-speed arterial roads, the walk signal should start as soon as possible after a pedestrian calls for a *Walk* signal if the phase for conflicting vehicles is not needed and may be safely terminated.

At many intersections, vehicles turning right are permitted to pass over an adjacent crosswalk during the walk signal after yielding to pedestrians. This quite common solution provides a green signal to right-turning vehicles at the same time the walk signal is displayed to pedestrians. The solution is acceptable if right-turn vehicles do not experience long queues caused by pedestrians blocking their movement. Otherwise, aggressive driver behavior resulting from long delays may expose pedestrians to an excessive risk of collision with a turning vehicle. The intersection corner negotiated by right-turning drivers must also be designed to be sufficiently sharp to slow drivers down and protect walking pedestrians. This measure is particularly important if a crosswalk is offset from the intersection and vehicles have a distance to accelerate before reaching it. On the other hand, if a crosswalk is immediately adjacent to the intersection, a turning vehicle may arrive at the crosswalk at the same time that pedestrians take their first steps onto the pavement. To avoid this potentially dangerous situation, the walk signal for pedestrians should start 2–3 s ahead of the vehicles' green signal to establish pedestrian presence on the crosswalk before arrival of the first vehicle. The visibility of pedestrians to drivers is of paramount importance. The corner should be clear of any sight obstructions such as bushes, kiosks, and advertising columns. Street lighting should provide sufficient illumination of any waiting and crossing pedestrians during dark hours. Separating a pedestrian signal phase from a signal phase for turning vehicles is a

recommendable solution where the vehicle–pedestrian conflict is considerable. The increased wait time for both parties makes signal violation more probable though.

Bicyclists at Signalized Intersections

Bicyclists are another group of vulnerable road users. One of the successful improvements for these road users are bicycle boxes and two-phase crossings for bicycles' left-turn movements. They typically require push buttons at actuated signals to call their signal if no motorized vehicles moving in the same direction are present. Otherwise, violating a red signal may be the only way for cyclists to avoid long waits or walking with the bicycle across the crosswalk. Also, if intersections do not have separate signal displays for bicyclists, the clearance phase for vehicle traffic should be designed for bicycle traffic and speeds around 12 mph (20 km/h) or lower where justified.

Signalized Crosswalks

Pedestrian and bicycle crossings on arterial roads may require traffic signals to mitigate the conflict between vulnerable road users and vehicular flows. Crosswalk and bicycle crossing signal design deserves the same, or, even higher, level of attention as vehicular signal design. To minimize signal violations by pedestrians, the best method is to provide walk signals as frequent and for as long as practical. The best signal coordination plan, from the point of view of pedestrians and bicycles, promotes vehicle groups from opposite directions to arrive at the crosswalk simultaneously in order to open as large a time window as possible for the pedestrians and cyclists to cross the road. If push buttons are provided to recall a signal, waiting for the walk signal should not be longer than the time needed for vehicles to clear the crosswalks, unless the call was placed in the part of the cycle reserved for the coordinated vehicular phase.

At signalized crosswalks without signal coordination, a fully actuated signal with push buttons for pedestrians and bicycles, and detectors for vehicles, allows signals to be set adequate to road user needs and priorities, as prompted by traffic volume and crash records. Particularly important for pedestrian and bicycle safety on high-speed arterials is prevention of the signalized crossing dilemma zone sometimes faced by arriving motorists. Protecting the safety of children crossing roads in school zone areas is of particular concern. It has been demonstrated that signalization of crosswalks in school zone areas may be an ineffective solution as children tend to violate signals while drivers may pay less attention at signalized than at unsignalized crosswalks.

Pedestrian Light CONtrolled (PELICON, then PELICAN) crossing was introduced in the United Kingdom, in 1969. It was the first pedestrian crossing located between intersections and protected with traffic signals. A similar solution, High-intensity Activated crossWALK (HAWK) is a type of crossing introduced in the United States. The HAWK beacons consist of two red lights on top and a yellow light on bottom for vehicles. The signals for vehicles are inactivate until a person presses a button on the signal pole and the yellow signal begins to flash. The flashing yellow turns to solid to prepare drivers to stop. The driver has to stop once both top lights turn solid red and pedestrians receive *Walk* signal. Pedestrians see standard *Walk* and *Do Not Walk* with optional time countdown. Drivers may pass the intersection when the two solid red signals turn to flashing and pedestrians have ended crossing for improving the safety of pedestrian crossings at locations where pedestrian volumes do not meet Manual on Uniform Traffic Control Devices (MUTCD) warrants for conventional traffic signals.

Protecting pedestrians and bicyclists from serious injuries and death on signalized crossing by reducing vehicle speeds of vehicles include raising the crossing area (Sweden) or painting zigzag lines on the approaches to the crosswalks (Great Britain). Other precautions to protect pedestrians and bicyclists include street lighting focused on the crosswalk, special signage to bring driver attention to the crosswalk, separation islands for pedestrians and bicyclists, speed limits, and display to pedestrians and bicyclists of the time countdown to the next walk signal.

Signal Preemption

Traffic signal preemption allows emergency vehicles, public transit vehicles, trains, and other vehicle types pass a signalized intersection or crossing without stopping or with minimum delay. Although signal preemption may be seen as a control intervention that disrupts regular operations, it is needed to provide priority to emergency and transit vehicles and to reduce the risk of collision.

Signal controllers are equipped with special devices that can receive a request from authorized users to activate preemption. Upon receiving a preemption request from an emergency vehicle, the preemption system overrides regular operations of the signal controller, forcing termination of the current signal phase and, after required clearance time, calling a signal phase that protects conflict-free passing through the intersection by the emergency vehicle. A similar operation is executed at traffic signals located near a railway crossing. To permit a safe train's passage, green signals that help clear the area and red signals that prevent motion of vehicles toward the railway crossing are called or extended. These signals are maintained from the period preceding the train arrival through the train passing the railway crossing. A preemption request is frequently sent automatically when emergency vehicles or trains are at predetermined distances from the required location in order to allow sufficient time for effective preemptive action.

Traffic signal preemption may include confirmation of the preemption to the requesting driver and a warning signal to other drivers. The warning signal is usually a single light placed near the intersection that is visible to all road users around the intersection, or it might be several directional signals aimed toward approaching traffic streams. The signals may flash or be continuous. A variety of solutions have been tested to inform local drivers where the emergency unit is coming from and which direction may need to be cleared. Since emergency preemptions at many locations are infrequent, it has been difficult to develop and disseminate among road users a general awareness of the notifying signals and knowledge of their meaning. Current and emerging in-vehicle technologies, however, bring an opportunity for transmitting emergency notifications directly to vehicles potentially affected by the preemption.

Preemption for prioritizing public transit is less intrusive as its main purpose is to reduce delays rather than improve safety.

Signals During Low-Volume Periods

Traffic control signals in the flashing mode may be a beneficial form of traffic control that increases driver awareness of an intersection's presence without interrupting traffic nor causing additional delays. For these reasons, traffic signals are often operated in flashing mode, with yellow flash on the major road and red flash on the minor road, during periods of low traffic volume during late-night and early-morning hours at intersections with adequate sight distance. Unfortunately, before/after research studies indicate a near doubling of crash rates when flashing signals of this type are implemented during these periods, as compared to the ordinary three-color operation. An alternative strategy is to make the intersection all-way stop during low-volume times with red flash on all approaches.

Eliminating Traffic Signals

Unwarranted installation of traffic signals at intersections may increase delays and reduce safety. A similar effect is also expected at signalized intersections when traffic signals are no longer justified after traffic volume has dropped below the level that would warrant the signals. This situation is possible if an alternative road has been opened that offers a more convenient connection with a major traffic attraction such as a nearby shopping mall, or when an attraction is closed. Elimination of signalization often requires redesigning the roadway geometry. This is a good opportunity to build a roundabout—one of the safest solutions for moderate or low-volume traffic.

Introduction

Tunnels constitute a significant building block for supporting an adequate and intelligent road network. There are different types of tunnels, such as road, rail, pedestrian, or bicycle tunnels. The latter are used to increase safety of pedestrians and cyclists who are trying to cross busy roads. However, such tunnels can create risks if they are poorly designed, not well lit or used improperly. On the contrary, rail tunnels also pose critical risks but, since there is no other “traffic” and train drivers do not interact with one another, the safety of rail tunnels is probably higher than that of road tunnels. This paper focuses on road tunnels and specifically examines the current best practices and challenges for risk assessment.

In general, road tunnels are divided into urban and rural depending on their different operational and construction characteristics. Urban tunnels are developed to improve transportation flow within cities. This includes the improvement of environmental quality of densely populated areas by easing traffic congestion and pollution. Thus, they are usually formed as underground constructions. On the contrary, rural tunnels are developed in order to reduce travel distances and increase safety by creating shortcuts in mountainous areas. Their importance is related to the fact that they minimize the environmental impact while reducing travel time and cost (Kirytopoulos et al., 2017). As a result of the significant improvement of underground construction-related technology in recent years, tunnels are nowadays a cost-effective engineering solution within road infrastructure. As a consequence, their numbers are increasing as more and more tunnels are developed, specifically in Asian countries due to the economic growth but also in Europe as part of the infrastructure enhancement, that, in turn, increases the number of people and the volume of goods transported through them (Ntzeremes and Kirytopoulos, 2019).

Despite the numerous advantages, tunnels bear an internal issue, which is the extreme impact of potential accidents. Undoubtedly, fire accidents are the biggest threat for tunnel systems since they can result in enormously adverse impacts regarding human losses and destruction of the tunnel’s equipment and infrastructure (Li and Ingason, 2018). The devastating experience from fire accidents in the past, such as Mont Blanc fire in France/Italy (1999; 39 fatalities) or the fire in Yanhou in China (2014; 31 fatalities), is indicative of the severity of such accidents. On top, such accidents will also bring significant economic losses and costs relevant to the rehabilitation of the infrastructure. The rapid growth of tunnels implies that more fire accidents may occur in the future, thus the development of efficient safety strategies is of utmost importance. Because of that, authorities and safety analysts around the world work on sophisticated, more effective safety strategies based on a risk-based approach in the tunnel area (Li and Ingason, 2018; NCHRP, 2011; PIARC, 2013).

Setting the Scene: Accidents and Fires in Tunnels

Tunnels, together with bridges, are the most advanced components of the road network. A quick look at tunnel facilities and equipment justifies this description. Nowadays, most long tunnels are continuously monitored through a control center. Complex surveillance systems for monitoring tunnel areas include systems using motion pattern sensors for detecting potential fire accidents

Table 1 Indicative road accident rates

Country	Accident rate in road tunnels	Accident rate on open road
Austria (data years 1999–2003)	10	14
France (data years <1998)	9	7
Norway (data years 2001–06)	12	>12
Greece (data years 2011–13)	4	6
Italy (data years 2006–09)	15	9

Data: Synthesis of multiple sources—values are approximate.

Accident rates per 10^8 vehicle-kilometres.

Note: The data are comparable only between road tunnels and open road per country and *not* across countries as the measurements are not always compatible since they may follow different protocols and different years.

and systems, such as the last generation devices, for smoke and temperature detection. These systems provide direct information on the location of an incident or fire and its development in order to enable assessment and appropriate execution of response protocols. Furthermore, advanced systems for controlling the development and consequences of a fire event, such as mechanical ventilation and fixed firefighting systems, enable tunnel staff to manage the system remotely from a control center and direct emergency services to rescue trapped users successfully and prevent damage to tunnel structure and facilities.

In general, tunnels are regarded as safe road facilities (Nvestad and Meyer, 2014). There are plenty of reasons for the increased safety in tunnels including drivers being more vigilant but also the standardized environment. For instance, apart from extreme cases, tunnels are not affected by weather conditions, they usually lack junctions, walkers, parked vehicles, bicyclists, or distracting advertisement stands, which are common causes of accidents or factors that affect an accident's evolution. Additionally, studies have indicated that users drive more carefully when passing through tunnels. In view of that, tunnels are perceived to be safer than open roads (Kirytopoulos et al., 2017); however, official statistics are not absolutely conclusive on that. For instance, as depicted in Table 1, Austria, Greece, and Norway exhibit a lower accident rate in road tunnels than on open roads, France has about equal rates in the two systems, while Italy has higher accident rates in tunnels than on open roads. Also, there are studies mentioning that although the accident rate in tunnels is lower, the severity of the accidents is higher. In translating these data though, one should keep in mind two important issues. The first is that safety, specifically in road tunnels, is constantly improving as new technologies are embedded into the tunnel systems. The second is that the actual monitoring and recording of accidents in tunnels is such that every single incident is captured while this might not always be the case for open roads.

In particular, fire accident rates are much lower in tunnels than on open roads. Indicatively, statistics from France show that there are fewer than two vehicle fires per tunnel kilometer traveled per 100 million vehicles ($<2/10^8$ vehicle-kilometres) (Beard and Carvel, 2012). When it comes to heavy goods vehicles, the index is increased to about $8/10^8$ vehicle-kilometres. However, only $1/10^8$ vehicle-kilometres is serious enough to cause any damage to the tunnel itself. In absolute numbers, for Norway, a country with more than 1000 tunnels, and with a combined length over 1000 km, the average number of tunnel fires sparking from vehicles is approximately 20 per year (Nvestad and Meyer, 2014). Only some of those will result in any harm to people, but it is still a serious concern for users. China features highway tunnels in more than 15,000 locations with a total length above 14,000 km. A sum of 161 fire accidents has been recorded over the last 15 years in China (Ren et al., 2019). The results indicate that over half of them were due to vehicles' technical problems.

In-depth studies have revealed some general conclusions regarding accidents in tunnels (Beard and Carvel, 2012; Kirytopoulos et al., 2017; Nvestad and Meyer, 2014):

- It is evident that bidirectional tunnels have higher accident rates than unidirectional ones. Moreover, the response to a fire in a bidirectional tunnel is much harder since vehicles typically get trapped both upstream and downstream of the fire, thus the typical ventilation systems cannot be used (pushing the smoke to either side will put some users in danger).
- The terminal zones are more prone to accidents than the central zones. This is related mostly to the changing conditions/geometry/environment, the black hole effect at the entry portal and the glaring at the exit portal.
- Higher accident rates are observed in sections that affect the traffic flow (e.g., speed changes, variations in alignment, etc.).
- Most accidents are caused by rear-end collisions, poor maintenance of vehicles, and disobedience by drivers in keeping a safe distance to vehicles in front.
- The prevailing causes for fires in road tunnels are collisions. That includes both collisions between vehicles and between vehicles and the tunnel structure. But fires are also caused by electromechanical issues such as overheated brakes.
- Users' behavior after fire ignition is decisive for the outcome in terms of injuries or losses. Quick self-evacuation is regarded to be the most important factor in mitigating the consequences of an accident as far as users' survival is concerned.

The potential severity of tunnel fires is related to some special attributes of the tunnel. The particular environment in tunnels exhibits: (1) the absence of natural light, in which drivers need to adjust, (2) directed and almost constant air movement because of the different pressure between tunnel portals that complicates the operation of ventilation, (3) difficulties for emergency services and rescue crews to approach the crash site in case of an accident, and (4) irregularities in fire combustion (Beard and Carvel, 2012; Nvestad and Meyer, 2014).

The last attribute is closely related to the challenges of properly modeling the fire and thus deciding on the right equipment to be installed in tunnels. It is not easy to model the fire behavior in a single way as fire is influenced by the different characteristics of the burning materials as well as the ventilation (Li and Ingason, 2018). Additionally, tunnels are different to one another. Tunnels can differ by being unidirectional or bidirectional, and have different geometrical characteristics (e.g., length, width, etc.), different structure, or traffic conditions (e.g., average volume, whether dangerous goods transportation is allowed, etc.). These differences influence fire development and evolution and consequently the appropriate safety strategy (Ntzeremes and Kirytopoulos, 2019). The enclosed environment affects both the fire and the smoke development owing to the mutual interactions between physical and chemical processes. Due to these interactions, tunnel fires are characterized by turbulence, combustion irregularity, and high radiation (Beard and Carvel, 2012). There is also the possibility of a quick fire spear between stopped vehicles. A fire spear occurs when fire is transmitted quickly from one car to the other when the cars have not kept the appropriate safety distance while stopping upstream the fire one behind the other. Furthermore, the oxygen required for combustion is not always available in tunnels as in the open environment. As a result, large amounts of toxic fumes and products of incomplete combustion are emitted inside the tunnel. These conditions create a highly unsafe environment for trapped users who are affected by the smoke even in cases of unidirectional tunnels, especially during the initial stage of the fire (before the ventilation system manages to push the smoke downstream of the fire) as hot gases and smoke flow upstream of the fire location create the well-known backlayering phenomenon (Li and Ingason, 2018; NCHRP, 2011).

Fire Safety in Road Tunnels: Fundamentals of the Risk-Based Approach

System Description and Theoretical Framework

The disastrous fire events that led policy-makers and safety experts to reconsider road tunnel safety were the serious Alpine accidents of Mont Blanc—France/Italy, 1999 (39 losses), Tauern—Austria, 1999 (12 losses), and St. Gotthard—Switzerland, 2001 (11 losses). Those tragedies remind us that tunnels should be considered complex socio-technical systems and that their safety is a very complex issue (PIARC, 2008, 2013).

A system consisting of technical, organizational, and social elements is a socio-technical one. Indeed, road tunnels involve human, organizational, and technical elements, and hence they can be understood as socio-technical systems (Kazaras and Kirytopoulos, 2013). They are complex systems since they can be influenced by the setting (environment) of operations and they also influence this setting in return. Road tunnels are open to transport and influence the area in which they are located by the transportation of people and goods. If a major tunnel accident occurs, this may significantly affect the nearby region. In this sense, tunnels can be regarded as complex socio-technical systems. The main issue with such systems, especially complex ones, is that their overall safety is dependent on many characteristics coming from the interaction of their components and not only by the isolated safety level of an individual component. In road tunnels, it is the complexity of the nonlinear interactions among the different elements of the system that characterize the overall system's safety. Modeling the complex tunnel system can, however, be simplified through grouping various system parameters into users, facilities, infrastructure, vehicles, and traffic characteristics (Ntzeremes and Kirytopoulos, 2019; PIARC, 2008).

Normative tunnel safety, especially in Europe, has changed drastically once the European Directive 2004/54/EC came into force (EC, 2004). Till then, tunnel systems were regarded as safe only if they were designed in line with the prescriptive regulatory requirements that each country had imposed. Given the deficiencies of prescriptive regulatory requirements to manage a complex socio-technical system, the new safety approach introduced in 2004 uses risk assessment along with adherence to normative requirements. This is the so-called risk-based approach, and it enables tunnel managers and safety analysts to better investigate the system and understand, assess, and manage any potential risks (Aven and Zio, 2014; PIARC, 2008). Hence, a proper safety approach toward tunnels does not count only on *learning from events* (which is the main source of prescriptive requirements), but also on *assessing the system proactively*, similar to roadway audits, as should be the case for any complex socio-technical system (Aven and Zio, 2014; Ntzeremes and Kirytopoulos, 2019). Current trends see the risk-based approach as a systemic approach including an in-depth examination of potential accidents as well as the observation of possible residual or concealed risks identified from past accidents.

Various risk assessment methods have been developed over the years. Many countries have developed their own methods. A brief report of such methods can be found in the World Road Association (formerly named PIARC) reports. There is also some work in methods developed from academia (INERIS, 2005; Kazaras and Kirytopoulos, 2013; Ntzeremes and Kirytopoulos, 2018). Despite which specific method is used, the general risk assessment framework consists of three discrete layers. After a top-to-bottom sequence, these layers are follows (Ntzeremes and Kirytopoulos, 2019; PIARC, 2008, 2013):

- Risk analysis, which forms the first layer of the framework. This layer consists of three sub-layers. The first sub-layer is the *system definition*. The better the tunnel system is defined, the better the goals of the analysis would be achieved. Subsequently, the next

sub-layer is the *hazard identification*. Hazard is defined as a *potential source of harm*. A combination of hazards can lead to the critical event such as fire, which can cause direct or indirect harm to tunnel users, damage to tunnel infrastructure and facilities, and paralyze the rest road network widely. The last sub-layer is the *risk estimation* that entails the measurement of risk according to probability of occurrence and relevant consequences.

- Risk evaluation, which focuses on determining whether estimated risks are acceptable or not. To do so, estimated risks are compared with certain predefined risk criteria.
- Risk treatment, which aims at mitigating or eliminating, if possible, nonacceptable risks. Through this process, a decision to treat risk is made by selecting additional to standard safety measures. In the end, risk analysis is repeated in order to reevaluate the new risk level of the system and examine whether the residual risk is acceptable.

The Scenario-Based Approach

Regardless of the particular features of the method being applied, each one enables safety analysts to mitigate both the relevant probabilities of occurrence and/or the expected consequences. However, the lack of a sufficient amount of accidents prevents the extraction of sufficient statistical information and thus the analysis tends to be consequences oriented (Ntzeremes et al., n.d.). Such an analysis is the scenario-based approach, in which the tunnel system is investigated under predetermined conditions. To do so, safety analysts rely on standardized fire scenarios. Although probabilities should play a role in determining the scenarios to be examined, the analysis itself of the scenarios considers only the impact, that is, expected losses associated with the occurrence of a possible critical event. Therefore, mitigating the fire risk is translated in mitigating primarily potential losses among tunnel users in case of fire. This approach considers the technical parameters and the fire scenarios and is completed with an evacuation model for the trapped users. Computational fluid dynamics is usually used to examine the evolution of the fire and the evacuation model reveals potential losses (Ronchi et al., 2012). Depending on the results, the analyst comes up with a number of potential additional measures in order to reduce the estimated risks.

The Case of Vehicles Carrying Dangerous Goods

Based on the Agreement of Dangerous goods in Roads (ADR), transported goods are separated between dangerous and non-dangerous goods. Following this division, risk assessment adopts a totally different approach depending on the kind of transported goods. Fire accidents with dangerous goods involvement are of significantly lower-frequency yet lead to much higher-consequence critical events that can cause multiple fatalities in a single event. Thus, risk here is recognized as societal, unlike risk deriving from fire accidents without dangerous goods involvement, which is recognized at an individual scale. Societal risks are the ones who can affect the general public and may result in multiple casualties (PIARC, 2013).

The most widely accepted risk assessment method used for dealing with accidents involving dangerous goods is the OECD/PIARC quantitative risk assessment model (QRAM) (INERIS, 2005). This model examines 13 predetermined scenarios concerning potential types/groupings of dangerous goods but in this case the probability of having such an accident is taken into consideration. Contrary to the scenario-based approach without the involvement of dangerous goods, this analysis includes historical data of relevant accident rates and potential consequences of such accidents. The outcome provides the relevant evaluation of their respective consequences in terms of fatalities (and/or injuries) and frequencies in the form of frequency/number of fatalities (F/N curves). The developed F/N curves are compared with predefined criteria and the level of the tunnel safety is estimated. Predefined criteria are either in the form of overall expected values or the As Low as Reasonable Practicable (ALARP) principle. The latter also considers the cost/benefit analysis by comparing the resources spent to reduce risk to the increase of the level of safety, making sure that the cost involved in reducing the risk further would not be grossly disproportionate to the benefit gained (Ntzeremes and Kiriopoulou, 2019).

Challenges in Current Practice

The Human Factor

Looking closer to the existing risk assessment methods, the quantitative approach is used, almost exclusively, in order to predict the fire events, examine the associated consequences, and estimate the overall level of safety of the system. This is mainly because the quantitative approach is easier to be measured against specific thresholds imposed by norms or legislation. However, the quantitative approach includes several challenges, the main of which is the challenge to accurately capture human behavior and specifically the modeling of either the trapped-users behavior or the performance of tunnel personnel in applying the response protocols (INERIS, 2005). Empirical studies of actual or intended users' behavior have revealed that the users ignore important safety rules for driving through or copying with emergency situations in tunnels (Fridolph et al., 2013; Kiriopoulou et al., 2017). Despite the efforts of tunnels' managers in educating the users, there is, still, plenty of work to be done.

Knowledge about users' behavior would enable the analysts to better estimate and improve road tunnels' level of safety. In general, the analysts need to estimate and take into account the actions that people take and the time it needs for these actions to be performed (including realization and implementation time) during evacuation (Ronchi et al., 2012). Although conducted studies

and full-scale experiments do provide some information regarding users' behavior, the available data about evacuation behavior and movement are still limited and relevant assumptions often raise criticism (INERIS, 2005). Frequently, oversimplified assumptions about the different stages of the evacuation process, the behavior of trapped users, and their speed in a smoke-filled tunnel are made during the use of relevant models. Therefore, the effectiveness of both risk analysis and risk evaluation can be challenged and the need for further research endeavors in this space is evident.

Because of these reasons, the idea of using qualitative methods, supplementary to the aforementioned quantitative ones, in a systemic way for analyzing road tunnels safety is gaining space.

Organization and System Degradation

A crucial part in the systemic analysis is the organizational aspects at the tunnel manager end. Based on the idea that road tunnels are complex socio-technical systems, it is essential to highlight that the organizational perspective (systems, culture, and procedures) significantly affects the overall safety of the tunnel system, since it sets the context in which the human element (both user and operator) takes decisions and the technical system operates.

The way tunnel facilities are organized and operating is different among countries. Nevertheless, there are some common aspects that have an effect on the level of safety. Such aspects include: (1) maintenance and inspection, (2) recruitment of operators, (3) training procedures, (4) preparation of emergency plans, (5) cooperation with the emergency services, and (6) analysis of past incidents and learning from events. In addition, the interface design of the tunnel control center and the systems available for detecting and controlling an event greatly affect the outcome of an emergency situation. All the aforementioned aspects are undeniably critical and the fact that they are seldom included in the analysis may hinder an accurate safety assessment process.

By following the system's theoretic perspective, the adaptation of the tunnel system over time needs to be considered as well (INERIS, 2005). Currently, during risk analysis it seems that there is no provision for differences that may occur between what was originally designed and the actual conditions after some time of operation. Lack of such a provision implies that systems are regarded to be fully functional and procedures followed always without any signs of degradation over time. This is probably a narrow perspective as variation or adaptation is an intrinsic characteristic of any system, especially systems including human and organizational components. The point is that degradation of systems does not happen accidentally but is attributed to specific factors that should be identified and then managed appropriately.

Deviating Provisions

Traditionally, safety analysts, after the evaluation of the estimated risk and if the risk is above the relevant thresholds, define a list of alternatives and make a decision that best meets the existing risk criteria. The use of absolute risk criteria means that the evaluation strategy requires well-established thresholds or risk targets being in line with the regulative requirements against which estimated risks are compared. Although the application of such criteria can be simple, the determination of such thresholds in order to define the acceptable level of risk has many difficulties. Also, thresholds need to be supported by reliable and up-to-date accident databases, otherwise they can lead to misleading results (Ntzeremes and Kirytopoulos, 2019; Ronchi et al., 2012).

One issue though is that not all risk assessment methods or regulations include the same reference conditions, which may lead to different results regarding the level of safety. That is, the same tunnel under different reference conditions and thresholds would appear as having a different level of safety and thus would require different additional measures. Because of that, a common approach through policies is suggested. It is to be acknowledged though that, in cases where cultural or other special characteristics (e.g., familiarity to tunnels or general road safety rules adherence in the country) dictate a different approach, this needs to be seriously taken into consideration and may allow for deviations from a common standard or policy.

Recommendations

Fire accidents are the biggest threat for tunnel systems since they may lead to severe impacts regarding human losses and destruction of tunnel's equipment and infrastructure. The devastating experience from fire accidents in the past is indicative of the severity of such accidents. Because tunnels are critical infrastructures of the road transportation system, potential tunnel fire accidents can be catastrophic. Thus, fire safety is a key issue for any tunnel project. Based on statistics, tunnels are not less safe than the rest of the road network, and fire accidents frequency particularly is much lower (Li and Ingason, 2018). However, the rapid growth of tunnels worldwide implies that more fire accidents may occur in the future. Thus, the development of efficient safety strategies is definitely needed but also a challenge. Despite the fact that a fire is probably the most impactful risk in a tunnel, it is far from being the only aspect of consideration and efforts should be put in reducing accident numbers and their severities in general.

Currently, legislation in most developed countries includes a periodical risk assessment of road tunnels (PIARC, 2008, 2013). Such assessment is usually done using a scenario-based approach or/and a probabilistic risk assessment when, for example, transportation of dangerous goods is examined. Both approaches are quantitative in nature and certain benchmarks are used in order to judge the safety level of a tunnel. Despite the benefits of such an approach, there are still some areas, crucial to safety of a socio-technical system such as a road tunnel, that a quantitative method cannot fully incorporate. Such areas include: the human factor, which relates to the behavior of the users and the tunnel personnel; the organization of tunnel safety, including training,

emergency plans, analysis of past incidents, and lessons learned; and the potential degradation of the system, that is the adverse changes that happen to the system reducing the overall level of safety over time (INERIS, 2005).

Another important issue is the current inconsistency between assumptions and thresholds mandated in different risk assessment methods. Different countries provide different assumptions for, say, the heat release rate or the speed of evacuation and, obviously, this results in inconsistent conclusions regarding the safety of the same tunnel, dependent on which method the analysts use. Worldwide organizations working with or responsible for road safety, such as PIARC, should (and do) significantly contribute toward the harmonization of relevant standards (Ntzeremes and Kirytopoulos, 2019).

Combining the benefits of the quantitative and qualitative analysis, creating common standards and adopting a holistic risk assessment view, will definitely contribute to safer tunnels and serve better the purposes of Vision Zero for safety in road infrastructure.

Introduction: Disrupting Transportation Disruptions

There are different events and hazards that can disrupt transportation systems (Kim et al., 2018b). There are many different components of the transportation system—users, vehicles, facilities, roadways, equipment, networks, and technologies vulnerable to disruption by natural, human, technological, and combined forces. Efforts to cope with, minimize and mitigate the harm from disruptions can improve the resilience of transportation systems. Transportation resilience is the capacity to absorb shocks, to respond quickly and effectively to threats, and to recover functionality so that services and the movements of people and goods are not interrupted. A harm-causing event may result in the reduction or temporary shutdown of services, but a resilient transportation system rebounds and recovers quickly.

The extent of disruption can be measured in terms of the downtime, loss of service, reductions in capacity, travel volumes, speed, convenience, and increased costs of travel. The impacts of disruption include the number of travelers, trips, origins, and destinations affected, along with trip purposes as well as other metrics related to travel time. It is useful to assess the vulnerabilities of the transportation network (Murray-Tuite and Mahmassani, 2004). Disruptions affect both mobility and the ability to travel from one point to another and accessibility or the ability to use a particular mode of travel (walk, bike, auto, transit, paratransit, marine, air, etc.). Disruptions can especially impact those with limited access to transportation or special physical or health needs. Disruptions need to be seen in the larger social and economic context of travel behavior (National Cooperative Research Program, 2012).

Characterizing Disruption

The most common disruptions to the transportation system occur from weather events (heavy rainfall, flooding, landslides, storms, etc.), accidents, and large special events (sporting, political, conventions, etc.). Other events such as power blackouts, terrorism, and infrastructure failures (bridge collapses, derailments, airline crashes, structural defects, etc.) can also lead to traffic diversions, closed roadways, cancellation of services, and other impacts to the transportation system. Disruptions can also be caused by heavy traffic, congestion, and delay caused by insufficient capacity or labor disputes. Disruptions can result from internal factors related to the management and use of resources, factors of production, and operations or from external factors related to regulatory, political, or environmental changes that affect the availability and price of energy, movement and shipping of goods and people across borders and jurisdictions, or other factors such as conflict, terrorism, or changes in trade policy.

Hazards can be characterized by various spatial and temporal scales (see Fig. 1). Spatial and Temporal Dimension of Disruptive Hazards with Implications for Transportation Agencies shows common potential disruptions to transportation systems according to micro-, meso-, synoptic and planetary spatial and temporal scales. Hazards depicted in red correspond to more frequent, immediate, localized hazards, while those in orange refer to middle range threats in spatial and temporal scales, while those in green refer to longer term threats in time and cover greater geographic distances. While tornadoes and thunderstorms are microscale events with both rapid onset and concentrated potential for harm, other hazards and threats such as climate change, intra-seasonal oscillations and ENSO (El Nino Southern Oscillation) cover larger spans of time and distance in terms of their onset and location of effects. It is more difficult to predict with precision, microscale events. These hazards often threaten life and property and require effective alert and warning systems. While with some weather-related hazards such as wildfire, riverine flooding, and mid-latitude cyclones, there may be more time to prepare and preposition assets for response and recovery and evacuate communities, these hazards may cover a much larger physical area, making it difficult to focus attention and increase levels of preparedness. Synoptic and planetary hazards suffer from the “out of sight, out of mind” perspective, so individuals, agencies and organizations and communities may lack the

Figure 1 Spatial and temporal dimension of disruptive hazards with implications for transportation agencies.

sense of urgency and commitment to address these hazards and threats. More immediate, localized and understandable threats may divert attention away from longer-range threats and hazards.

While there may be time to prepare for and develop mitigation and adaptation strategies for climate change, much of the attention of the disaster and emergency management profession focuses on response and recovery from more immediate harm causing events. Moreover, threats associated with man-made hazards such as terrorism and industrial accidents have gained prominence since 9/11 and the Fukushima nuclear disaster. While the loss of life and economic losses associated with natural hazards is far greater, there is more attention to man-made threats as evidenced by the investments in the creation of the Department of Homeland Security and the Transportation Safety Administration ([Transportation Security Administration, 2018](#)).

Risk is the product of the likelihood and the consequences of hazards. There are frequently occurring, low consequence events and also rare, high consequence events. The management of risk involves understanding of both frequency and consequence of hazards.

Weather hazards are the most common type of disruption because weather varies greatly. Heavy rainfall, flooding, snow, and ice, and hazards such as landslides, avalanches, or downed trees and powerlines, or high winds can cause loss of vehicle control and accidents.

A seemingly minor weather event can cause major disruption such as in January 2014 when a few inches of snow fell in Atlanta ([Kim et al., 2018b](#)). While the National Weather Service had issued storm warnings, effort to plow and salt the roadways were hampered by lack of equipment, experience, and congestion caused by the early release of government employees and accidents, causing massive delays in a region which experiences severe peak traffic congestion even on days with good weather. Because of stalled vehicles, blocked roadways, and interrupted school bus transportation, students and teachers were forced to shelter in schools and other locations. A crisis situation was created because the disruption affected the travel of school children.

The largest disruptions to the transportation system result from big tropical storms and hurricanes, which may impact vast areas such as when Hurricane Katrina or Sandy struck. Hurricanes produce a combination of hazards and threats. In addition to damaging winds, storm surge, heavy rainfall, flooding, and the failure of power, water, wastewater, and other infrastructure systems can harm people and lead to the loss of property, roads, and other infrastructure. With Sandy, tunnels were flooded and closed, transit system equipment was damaged, and transportation services throughout the region were curtailed. Throughout the region hundreds of thousands of vehicles were damaged or destroyed. The towing, storage, repair, and disposal of damaged vehicles also present challenges.

While weather is the most common occurring hazard, there are also geophysical events and processes including volcanoes ([Ulfarsson and Unger, 2014](#)), earthquakes ([Sherrouse and Hester, 2008](#)), landslides, and other events which can significantly disrupt travel behavior. In some cases, such as when the Kilauea volcano erupted in Hawaii, the disruption is localized, affecting commuters, residents, and businesses because of damage to roads or because of evacuation orders requiring people to leave their homes or business or preventing students, workers, customers, tourists, or travelers engaged in recreational or social activities from

completing their trips (Kim et al., 2018a). These damaging events could lead to the rerouting of traffic or repositioning of schools, solid waste transfer sites, emergency services, and other activity centers.

With some volcanic events, the hazard is long-lived, lasting for weeks, months, or years. In addition to the lava threats, there are also concerns associated with volcanic gas, ash and other hazards such as acid rain which can harm human health, livestock, and agriculture. This can lead to the disruption of social and economic activities resulting in changes in travel behavior. The Icelandic volcanic eruption in 2010 led to more than 100,000 flight cancellations, millions of stranded airline passengers, and over \$1.7 billion in losses to the airlines. Geologic hazards are difficult to predict because the active forces can be located below ground and are difficult to detect, monitor, and map with precision. By the time an earthquake or ground deformation occurs, there may be only seconds to react and take protective action. Another challenge with earthquakes is that they can lead to cascading effects such as when the Great Japan Earthquake in 2011 led to a tsunami in which thousands of people drowned and flooded the Daichi Nuclear Power Plant, causing overheating of reactors, explosions and the release of radioactive material into the environment.

Different hazards and threats impact different transportation modes, facilities, and systems in different ways. Accidents involving motor vehicles and collisions with pedestrians, bicyclists and other roadway users are common events, which injure and harm people and cause disruptions, delay, and curtailment of transportation services. Coupled with fire or a hazardous materials spill, an accident can further harm individuals and the environment. Collisions with bridges, utility poles, roadside equipment or people lead to the need for accident investigation, repair work, environmental remediation, and construction work which could further interfere with the movement of people, goods, and vehicles. Accidents involve human, vehicle, roadway, and environmental factors. While most accidents are unintentional, there are examples of vehicles such as trucks or airplanes being weaponized to cause harm and governments have developed comprehensive strategies for reducing the threats from terrorism (Transportation Security Administration, 2018).

Accidents can result from the collapse of infrastructure such as when the Interstate 35 West Bridge connecting Minneapolis and St. Paul had a structural failure, causing 1000 feet of the eight-lane bridge to plummet into the river below (Kim et al., 2018b). This disaster occurred during the peak evening rush hour at 6:07 p.m. and resulted in 13 fatalities and more than 140 injuries. The National Transportation Safety Board determined the cause was the result of both design defects and improper inspection and maintenance practices (Hao, 2010). The disruption impacted not just motorists but also pedestrians, bicyclists, rail, and river traffic. Improper maintenance and repair of aging infrastructure is another hazard, which can result in significant disruption.

Special events can cause disruption of transportation systems. These are planned large sporting events, conventions and meetings, celebrations, parades, and special occasions. Often, they are regulated, permitted events such as the Boston Marathon which was impacted by terrorism when two homemade bombs exploded on April 15, 2013. Three people were killed and hundreds were injured. In addition to disrupting the marathon and impacting participants and spectators, the massive manhunt for the terrorists launched a few days later, led to the closure of the transit system, Amtrak service, as well as schools and businesses were closed as a city-wide, shelter-in-place order was implemented. There were significant economic impacts associated with the shutdown of transportation services affecting thousands of workers, customers, and residents of the region.

Coping with and Mitigating Disruption

Individual Strategies

When travelers encounter disruption, they can implement coping strategies. If possible, they change their route to avoid impassable areas or delay causing congestion. If the disruptions are known or planned events, they can change departure times, leaving either earlier or later to avoid slowdowns, road closures, or system shutdowns. Postponement or cancellation of trips can be facilitated by flextime, work from home, telecommuting, and improvements in communications and other technologies that support adjustments in travel behavior. Yet for some work, educational, and social activities, it may not be possible to avoid travel and face-to-face interactions. This may require the traveler to change destinations or change the travel mode, switching from surface to air transport or from ground based to marine travel. In some cases, travelers may need to switch from driving private automobiles to transit, shared ride, or combined modalities (walk, rideshare, bus, rail, etc.) to get to their destinations. In some instances, nonessential travel can be cancelled or deferred to a later time. Trips such as shopping can be accommodated with delivery services or other arrangements with suppliers as well as alternative providers of goods and services. Depending on the type and duration of disruption, the impacts on cost, convenience, consumers, and livelihoods can vary widely.

Of special concern is the effect of transportation disruption on evacuation. Disrupted or damaged transportation systems may strand evacuees or require rescue or assistance to move people, pets, and possessions to safety. Closed roads, cancellation of transit services, and decreased accessibility can also impair the ability of transit workers and service providers to get to work and operate vehicles, equipment, and facilities.

Agency and Organizational Strategies

Agencies and service providers need contingency plans, emergency operations procedures, and protocol for detecting and managing disruption. It is useful to consider both frequently occurring, low impact events such as heavy rainfall, power outages, accidents as well as rare, high consequence events including terroristic acts, earthquakes, flooding, and major disruptions leading to full or partial

shutdown of transportation systems. The experiences from managing smaller events are relevant to management of larger, more disruptive events. Often, the same personnel involved in operations and responding to hazards, threats, and system disruptions will need to be called upon for situational awareness, damage assessment, search and rescue, crowd management, and effective incident management.

In order to prepare for transportation disruptions, agencies and organizations must understand how to manage incidents, communicate and coordinate with other emergency response agencies (law enforcement, fire, emergency medical services, and others involved in disaster response). They must learn to optimize resources to reduce the harm from disruptions (Grayson and Noonan, 2010). For large-scale incidents, it may be necessary to call upon other agencies, jurisdictions, and assets from state and national agencies including the military to provide assistance, mutual aid, human and technical resources to support incident management. The I-35W Bridge collapse brought first responders from multiple local jurisdictions and required coordination between local, state, and federal authorities involved in search and rescue as well as the restoration and recovery of transportation services. A key to the effectiveness of the response to this disaster was training of personnel on Incident Command System, National Incident Management System (NIMS) and operating procedures, policies, and guidance for coordinated command and communications for emergencies and disasters. Implemented after the 9/11 terrorist attacks, NIMS is a method for managing response operations across all types of hazards and threats so that different agencies and jurisdictions can work together effectively. NIMS provides a framework for operations, planning, logistics, and financial administration, that is flexible, scalable, and makes the use of common definitions and terminology so that diverse personnel coming from different disciplines, agencies, jurisdictions, and levels of government can function together (U.S. Department of Homeland Security, 2019a, 2019b).

To reduce the impacts of disruptions, it is important for agencies and organizations to invest in drills, exercises, training, education, and capacity building in order to detect, communicate, manage, respond to and recover from disruptions. The training needs to be linked to risk and vulnerability assessments and the identification of potential hazards and threats and assets for response and recovery. In addition to building on the experiences from accidents and minor incidents, agencies and organizations conduct joint evaluations, after-action reports (Federal Emergency Management Agency, 2017), and “hot washes” to identify and categorize lessons learned as well as understanding of the materials, equipment, personnel, procedures, and policies needed to increase effectiveness and the capacity to manage disruptions and improve coordination across agencies (DeBlasio et al., 2004). The experiences of similar agencies experiencing common threats should be shared more widely across the transportation industry. Such evaluations should be conducted after disruptive events and following simulations or exercises designed to improve response and recovery capabilities. Transportation agencies and organizations need to create a culture of preparedness and to support investment in training and education for leaders, managers, and operational personnel.

Community Strategies

Effective response to disruptions involves communication and coordination with many different stakeholders. In addition to managers and field supervisors and system operators, it is important to work with and establish relationships with law enforcement, fire and emergency medical services and other responders (hazmat teams, urban search and rescue, utilities, etc.) which may be providing aid and assistance in the event of disruptive incidents. It is also important to focus on vulnerable, special needs populations which may require assistance in evacuation or transport to medical and care facilities.

Large incidents with multiple injuries and fatalities may require triage and additional transportation assets and personnel to manage care and the needs of victims, survivors, and affected people. In addition to physical and medical conditions, there may also be other social, cultural, language, psychological, and human needs of those affected by disruption. People may need to communicate with family members, friends, or employers. Travelers involved in accidents or incidents leading to damaged vehicles or equipment may need to find alternative modes to complete their journey or to manage the removal or towing of personal vehicles and may need to complete accident investigation forms working with law enforcement, insurers, and others involved in damage assessment and determination of the cause or “fault” associated with the incident.

For terroristic and intentionally caused incidents, the location may be treated as a crime scene in which evidence may need to be collected, analyzed, and preserved for further investigative or judicial action, such as immediately following the Boston Marathon bombing (Kim et al., 2018b). In these incidents, transportation officials will need to work closely with incident commanders and on-scene investigators who need to collect data and information from witnesses as well as physical evidence which can degrade quickly over time.

Large incidents may require the provision of on-scene medical as well as mass care (food, water, clothing, shelter, etc.) for victims, bystanders, and others (businesses, workers, etc.) impacted by a harmful event. In addition to government, various humanitarian assistance, nongovernmental organizations such as the Red Cross and faith-based organizations and spontaneous volunteer groups may materialize to render aid and assistance. With a large disaster, there may be volunteer rescuers such as the “Cajun Navy” or the evacuation of lower Manhattan following 9/11. For long duration disasters and disruptions such as volcanic eruption (Kim et al., 2018a) or events which lead to the longer-term displacement of residents and businesses, there may need to additional assistance and support during the restoration and recovery process (Kim et al., 2019).

Large incidents which damage infrastructure, buildings, and homes may create long-term disruptions to not just travel behavior, but also to the underlying social and economic activities for which the transportation system is designed to support. There may need to be adjustments or temporary services to accommodate transportation during the reconstruction phase. With disasters such as the

release of radioactive material following the tsunami in Japan, the cleanup and environmental remediation may take decades forcing long-term displacement of residents and businesses, prolonging the recovery for affected communities.

While individual travelers and transportation agencies can take steps to increase their preparedness and resilience to harm causing events, there is also a need for collective, community action to minimize the potential for disruption. This includes the planning for and mitigation and adaptation to hazards and threats such as climate change, urbanization, and stressors which increase the potential for harm to communities. In addition to identifying the risks of global warming, sea level rise, intensification of weather events, there is need for research and development of new materials and approaches to making transportation systems more durable, resistant, and stronger but also able to withstand and recover from flooding, wind, and seismic events (Asam et al., 2015). There is also need to invest in the development of robust supply chains to manage the flow of goods and services during and after disruptive events so that needed supplies and personnel can move quickly and efficiently across networks which may also be affected by disruption (U.S. Department of Homeland Security, 2019a). While these are large challenges related to social, economic, and geo-political forces, it is necessary to develop understanding of resource flows and effective strategies and actions for managing both the impacts as well as the systemic causes of disruption.

Small disruptions result from routine, more manageable incidents. Larger disruptions are caused by exogenous and global forces and require more extensive collective, collaborative efforts, agreements, and actions across regions, nations, and international partners. International scientific organizations such as the World Meteorological Association or the accords and agreements for sharing data on seismic hazards, volcanoes, tsunamis, etc. provide not just a basis for scientific advancement, but also opportunities to improve detect and warning systems as well as reduce stressors and social conflict arising from inequities and unbalanced concentration of wealth, resources, and economic opportunity. Transportation systems are major consumers of fossil fuels, contribute significantly to greenhouse gas emissions and global warming, exacerbating the potential for large-scale disruption of the climate system. There is, however, time and opportunity to reduce carbon footprints and the potential harm to transportation systems (Asam et al., 2015) and the communities they serve.

Key Lessons and Conclusions

Five key lessons emerge from this discussion on the effects and responses to transportation disruptions. They include the following:

1. anticipate the unanticipated,
2. focus on vulnerabilities and vulnerable populations,
3. agility = resilience,
4. learn from disruptive events, and
5. invest in research, training, and education.

Transportation agencies can avoid the unmanageable if they can learn to anticipate disruptive forces and manage unavoidable impacts to vulnerable populations. Those facing mobility and societal challenges are likely to be most severely impacted by disruptions. The physical components (vehicles, equipment, hardware) of the transportation system also need routine maintenance and upgrading. Transportation service providers need to avoid “unmanageable” incidents with complex, cascading effects such as the Fukushima disaster, which overwhelm local capacity and require outside assistance. They also need to manage “unavoidable” routine events such as accidents and flooding by anticipating and learning from disruptive events to address system vulnerabilities. Investments in research and capacity building promote greater understanding, agility and resilience.

In addition to plausible worst-case scenarios, transportation agencies should also anticipate the unanticipated. This includes studying catastrophic events that have happened in other jurisdictions and researching cases and best practices (American Association of State Highway and Transportation Officials, 2015). Prior to 9/11, there was little awareness of the potential for weaponization of transportation assets. The potential for disruption to the airline industry from the volcanic eruptions in Iceland was also not anticipated. The effects of other “creeping” disasters such as wildfires or sea level rise or increased storm intensities also need to be better anticipated and addressed in the planning, design, engineering, financing, construction, and maintenance of transportation systems. This may include planning, design, and construction of new seawalls or other infrastructure to mitigate harm from hazards. See for example, the work done in Virginia on the vulnerabilities of roads to storm surge and sea level rise (Kleinosky et al., 2006). Increased threats associated with cybercrime and the potential for disruption to transportation systems also need to be mitigated. Development of new technologies included connected and automated vehicles create new vulnerabilities. In addition to aging systems, the risks and vulnerabilities associated with new hardware and communications platforms (mobile, satellite, 5G, etc.) will need to be integrated into risk management. Such investments will require larger collective action across diverse constituencies and stakeholders who need to be better informed as to the benefits and returns on investment in resilient transportation systems.

A key element to minimizing the impacts of disruption is to focus on vulnerable populations and weaknesses in vehicles, facilities, and transportation systems. This involves strengthening facilities and structures to withstand earthquakes and tornadoes and other hazards. Components prone to breakdown require more maintenance as well as the stockpiling of spare parts. There is not enough attention to special needs populations as well as those with limited access and barriers to transportation assets due to medical, social, and economic conditions. There is need for reserve capacity and support services during incidents and disruptions (Cats and Jenelius, 2015). More attention to paratransit operations during disruptions as well as accommodation of the needs of

persons with disabilities, medical conditions, mobility limitations, and social barriers because of race, gender, age, or other factors needs to be a priority in the planning for and management of transportation disruptions. This requires closer coordination with social service providers and other partners handling special needs transportation services during and after disruptive events. With ridesharing, ride hailing services, the landscape of transportation service providers has changed greatly (Goodall and Lee, 2019). More attention to vehicle design, context sensitive design, accessibility, and transportation services for all will also have payback for the management of transportation disruption.

An important aspect of transportation resilience is the agility of travelers, agencies, and communities in responding to and recovering from disruption. Agility involves flexibility but also surplus capacity and resources which can be called upon when needed. It requires not just robust people and systems with effective technologies for seeing, sensing, detecting and assessing disruptions, but also effective communications between system operators, passengers, and first responders and others engaged in evacuation, sheltering, search and rescue and recovery. Agility involves not just speed, but also effective coordination and timely action to control vehicles, facilities, as well as manage crowds and those involved in the provision of emergency services.

Learning from disruptive events (Donahue and Tuohy, 2006) provides opportunity to study the causes and remedies associated with large and small disruptions. It is useful to look across a wide variety of different hazards and threats and consider how best to prepare, respond to, and mitigate the harm and impacts associated with natural and human caused incidents. Smaller, more routine events such as accidents or criminal activity demonstrate response capabilities and the technologies and systems for detection, alert, and warning and protocol for emergency response and system recovery (Goodall and Lee, 2019). The same personnel will likely be involved in the response and recovery from larger more disruptive events. Disruptions can be measured (Murray-Tuite and Mahmassani, 2004) in terms of the extent to which service is delayed, cancelled or closed, or degraded in terms of the number of travelers, travel times, mode changes, trip completions, inconvenience, and other measurable indicators of level of service. This is the basis for identifying vulnerable locations, links, nodes, and networks. Running plausible, worst case disruption scenarios due to weather, intentional acts of sabotage, accidents, or equipment and infrastructure failure due to poor design or inadequate maintenance is part of the effort to learn from disruptions and promote a culture of preparedness. Such efforts should include not just operators and managers, but the whole community of responders, caregivers, and volunteers who mobilize during disasters and disruptive events.

More attention to research, education and training is needed to promote understanding of disruption and the development of capabilities to reduce the effects on travelers and communities. In addition to studying and documenting the impacts and best practices with regard to different disruptions, there is need for interdisciplinary, international exchange of knowledge, technologies, and tools for detecting and alerting system users as well as for those involved in the planning, design, and operation of transportation services. In addition to better integration between routine operations and understanding of the management of congestion, incidents, and disruptions, it is necessary to encourage more testing and evaluation of procedures and actions in the event of disruptions. An emphasis on training and education of those in the transportation industry as well as more broadly in the communities at-risk from hazards and threats will serve to promote greater agility and resilience.

Biography

Karl Kim is Professor of Urban and Regional Planning at the University of Hawaii at Manoa, and Director of the graduate program in Disaster Management and Humanitarian Assistance. He studies transportation, cities, and resilience. He served as the Chief Academic Officer (Vice Chancellor for Academic Affairs) overseeing tenure and promotion, strategic planning, international programs and program review for the University of Hawaii. He is Executive Director of the National Disaster Preparedness Training Center (ndptc.hawaii.edu), authorized by the US Congress to develop and deliver FEMA certified training courses for underserved, at-risk communities on natural hazards, mitigation, and urban planning. The Center has trained more than 50,000 first responders, emergency managers and leaders in over 400 different communities across the world. Dr. Kim has served as the Chairman of the National Domestic Preparedness Consortium (ndpc.us). He has published many papers on disaster management, transportation, and urban planning. He is Editor-in-Chief of *Transportation Research Interdisciplinary Perspectives* (Elsevier) and is editor of a 10-volume series on disaster risk reduction and resilience (Routledge). He has been a Fulbright Scholar to Korea and the Russian Far East. Dr. Kim was educated at Brown University and the Massachusetts Institute of Technology.

Crash Data Modeling, Methodological Issues, and Data Limitations

Various statistical models have been proposed to model the frequency and severity of crash data (Lord and Mannering, 2010; Lord et al., 2021; Mannering and Bhat, 2014; Savolainen et al., 2011). Crash data are often over dispersed, which means that the variance of crash data is greater than its mean. Therefore, the Poisson distribution which is often used to model the data characterized by an equal mean and variance is not a suitable choice for crash data modeling. The Negative Binomial (NB)—also known as Poisson-gamma—is the most common model used to analyze over-dispersed (i.e., variance > mean) crash data. The Negative Binomial model is a mixture of Poisson and gamma distributions. The gamma distribution gives additional flexibility to the Poisson distribution to accommodate the over dispersed data.

Although the NB model is the most common model used to model crash frequency, it is not without limitations. In fact, there are several methodological issues with the NB model. As such, the NB model is not adequate for modeling data with many zero observations (Geedipally et al., 2012; Lord and Geedipally, 2011; Lord and Mannering, 2010; Shirazi et al., 2016, 2017), or accounting unobserved heterogeneity (Mannering et al., 2016). On rare occasions, also, the mean of crash data might be greater than its variance, or in other words, the crash data are under-dispersed, which usually occurs due to the data generating process (Lord and Mannering, 2010; Lord et al., 2021). In this scenario, the NB model is no longer appropriate and other models that can accommodate data with a variance less than the mean such as Conway–Maxwell–Poisson model (Lord et al. 2008; Lord et al., 2010) are recommended to be used. In addition, data may be characterized by the bias caused by a low sample mean and a small sample size. Lord and Mannering (2010) listed three major reasons that leads to a dataset with a low sample mean and a small sample size. First, there are data collection limitations. Collecting safety data is expensive and requires significant time and resources. Hence, collecting all data may not be economically possible. Second, this issue can occur when analyzing unique and rare facility types. In fact, some facility types are so unique and rare in the jurisdiction under study that the analyst does not have access to enough number of sites or locations, to collect adequate data to develop a reliable model. Third, datasets can be characterized by excessive zero observations. In addition to the methodological issues caused by data characterized by many zero observations (as noted above), excessive zero observations in data can also result in a low sample mean and a long tail which adversely affect the performance of the model. Data characterized by a low sample-mean and a small sample size result in inaccurate estimation of the NB dispersion parameter (Lord, 2006; Lord and Miranda-Moreno, 2008).

Before describing data limitations and modeling issues with underreported crash data, it is important to discuss one more important modeling issue that should not be confused or mixed with the underreporting of crash data. This issue is referred to as the omitted variable bias in statistical analysis. Omitted variable bias refers to instances when some important independent variables are not included in the model, which can cause significant bias or inaccuracy in the modeling results. A positive bias and over estimation of parameters happen when both of the independent and dependent variables are positively (or negatively) correlated with the omitted variable. On the other hand, a negative bias occurs when the dependent variable is positively (or negatively) and independent variables are negatively (or positively) correlated with the omitted variable. Omitted variable bias result in inaccuracy in parameter estimations, and consequently leads to incorrect crash predictions, and erroneous safety evaluations and analyses.

As a closing note to this section, it is worth pointing out that, regardless of the type of the model or the method used for the safety analysis, modeling itself is not a trivial task and involves different steps and nuances, from data collection to cleaning the data to estimating, evaluating and selecting the best model. Various questions should be answered by the analyst when he or she works with the data during the modeling phase. For example, should he or she use a panel or cross sectional data? What should be the functional form? What variables should be used in the model? What is the best model? All these questions should be answered one by one during the modeling process. A final model is usually selected based on comparing several alternative models and considering multiple modeling objectives such as goodness of fit, the intuitive relationships between the response and variables, goodness of logic (as explained by Lord et al., 2021; Miaou and Lord, 2003; Shirazi et al., 2017; Shirazi and Lord, 2019) and prediction accuracy.

Underreporting of Crash Data

Crash data recorded by law enforcement are considered as the primary source of information in analyzing crash data and evaluating safety. However, not all crashes are reported in police records. As such, in most jurisdictions, a minimum threshold needs to be met to include a crash in official statistics. For example, a crash must have caused \$1200 or more in damages to be reported. In fact, incomplete reporting of crashes in official statistics has been a critical issue in analyzing crash data for decades (Elvik and Mysen, 1999). The severity of crashes is typically classified in ordinal scales using five categories: fatal injury (K), incapacitating injury (A), nonincapacitating injury (B), possible injury (C) and property damage only (PDO). While in most developed countries, fatal crashes have been properly defined and carefully reported, the same cannot be said for nonfatal crashes. Reviewing 18 different studies, Hauer and Hakkert (1988) estimated an underreporting rate of less than 5% for fatal crashes, but they estimated much higher rates for the less severe crashes. Hauer and Hakkert (1988) pointed out that approximately 20% of severe injuries, and 50% of all injuries are often not reported. In another study, Alsop and Langley (2001) noted that only about two-thirds of hospitalized crashes were reported by law enforcement in New Zealand in 1995. The level of underreporting of accident data can induce uncertainty about the modeling and analysis of crash data and result in significant bias in estimation of model coefficients.

Wood et al. (2016) documented several factors that influence underreporting of crash data. First, and probably by far the most critical criteria, the extent of the damage to the vehicle. As noted above, each jurisdiction has a certain threshold to report crashes. If it is a minor crash, and the damage is below the reporting threshold, the crash will not be reported in official statistics. Second, drivers' willingness to report the crash. For instance, a driver involved in a PDO collision (above the minimum reportable threshold) may choose to pay the damage him or herself and not report the accident to authorities (e.g., law enforcement or his or her insurance company), in fear of penalty for committed violations or that his or her insurance premium may go up. Finally, yet importantly, the officer may deem the crash minor and does not file the report.

In addition to the above factors, the jurisdiction or the area where the crash occurs can also influence the underreporting rate. In fact, a case study in France (Amoros et al., 2006) showed that the underreporting rate varies based on the crash area (e.g., urban vs. rural or remote locations). In addition, even the road type and the police availability in the area considered as a major factor influencing the underreporting rate. The research studies also analyzed the relationship between various demographic factors with underreporting rates. While not all demographic factors are correlated with the level of underreporting, there are strong correlations between some of these factors and underreporting rate. For example, Alsop and Langley (2001) noted that the underreporting rate varies by the age of participants in New Zealand crashes. On the other hand, they concluded that the gender or race of participants are not significant factors. Last but not least, the time of crash and the number of vehicles involved in a crash are also considered as two additional factors, apart from severity levels (e.g., minor crashes are not completely reported) and geographical locations (urban vs rural), that influence the underreporting of crash data (Alsop and Langley, 2001). For example, crashes are more likely to remain unreported at nights or some months of the year, or the crashes that involve two or more vehicles are more likely to be reported than those that involve only one vehicle.

As a closing note to this section, it is also worth noting that in the United States, crash records collected or managed at the National Highway Traffic Safety Administration (NHTSA) and all departments of transportation (DOTs) include only crashes that involve motor vehicles and only crashes that occur on public roads (or in some states, like Maine, on public roads or in private areas where public traffic is anticipated, such as in Walmart parking lots). So, it may not be surprising to notice that traffic injuries involving bicyclists but not motor vehicles are not collected or compiled by governmental agencies. Even motor vehicle–bicycle crashes may not be reported to (or by) the police since the motorist may drive the bicyclist to the emergency room (ER) without involving the law enforcement.

Estimation of Underreporting Rate

The previous section described the issue with the underreporting of crashes, and how underreporting seems inevitable due to various factors. The next question is whether or not we can estimate the underreporting rate, and to what extent we can achieve this goal. This section reviews the methods and data sources used to estimate the underreporting rate.

Earlier studies mostly estimated or determined the underreporting rate by comparing the statistics recorded in hospitals or emergency rooms with those reported by law enforcement. For example, Aptel et al. (1999) found that there was a 62.7% discrepancy in nonfatal injury crashes between hospital data and police records. However, although initially considered a promising approach, comparing the hospital records and law enforcement data may not be sufficient to provide an accurate estimation of the underreporting rate. Several reasons were noted in safety literature to justify this claim (Aptel et al., 1999; Elvik and Mysen, 1999). First, hospital records are not without limitations themselves and are also likely to be incomplete, similar to the police records. Second, the source of injury in patient files or hospital records may not be clear or could contain mistakes. Also, privacy rules may mean that the crash location and other pertinent data cannot be easily obtained. Third, there might be a significant regional discrepancy between the regions where the crash occurs and where an injured person is hospitalized which will add substantial level of difficulty to determine the bias caused by underreporting, or estimate the underreporting rate. Last but not least, the definitions used in hospitals and police records may not be consistent and can be incompatible with each other. One advantage with hospital records is that E-codes, N-codes and AIS-scales are identically defined around the world whereas the definition of evident injury may vary from country to country and even within countries.

Despite these limitations, however, still hospital or emergency room records are used as a major source of information to estimate the underreporting rate. In fact, hospital or emergency room records might provide satisfactory results to estimate the underreporting rate for some types of crashes. For instance, [Janstrup et al. \(2016\)](#) used data reported in police records, and those collected from the emergency rooms to find out—given a set of variables—what type of crashes are more likely to appear on both police and hospital records. The study found that crashes associated with the use of helmet or seat belt, or those related to the alcohol usage or speeding are more likely to appear on both police and hospital records. As another example, In Sweden, the Swedish Traffic Accident Data Acquisition (STRADA) system ([OECD, 2019](#)) deploys a systematic connection between the law enforcement records (crash information) and hospital data (medical information) to provide greater accuracy in reporting severe crashes (fatal and serious injury crashes). However, although STRADA system is often reliable for serious injury crashes, the less severe crashes (e.g., minor injuries that only need primary care) are likely to remain underreported in the system.

Research studies resorted to other sources of data such as those collected by insurance companies to determine the underreporting rate as well. However, using other supplementary data such as insurance records can also be inadequate to determine the level of underreporting, as these sources are also likely to be incomplete or inconsistent with law enforcement records. For example, as noted above, it is likely that a driver decides not to report a minor crash to both his or her insurance company and law enforcement in fear to see a raise in insurance premiums or to be considered guilty for committed violations. In order to obtain more robust results, several studies have attempted to estimate the underreporting rate or alleviate the bias caused by underreporting using data from multiple sources. For example, [Watson et al. \(2015\)](#) merged and combined several data sources collected in Queensland, Australia to estimate the degree of underreporting in crash injuries reported by the police department. Data used for this purpose include the Queensland road crash database, admitted patients in Queensland hospitals, data from the emergency department information system, and data provided by the Queensland injury surveillance units. Using all these data, merged and combined, the researchers found that around two-third of injury crashes were not reported in statistics reported by law enforcement. Further analysis revealed that the extent of underreporting is larger in crashes involved bicycles or motorcycles, as well as those occurring in remote locations.

Crowdsourcing is another approach that was recently suggested by researchers. Crowdsourcing (e.g., Web-based mapping or GPS-enabled mobile devices) brings new avenues for data collection compared to traditional datasets that can be used in addition to the archived data to explain, analyze or estimate a phenomenon ([Lord et al., 2021](#)). [Medury et al. \(2019\)](#) used crowdsourcing to estimate underreporting in pedestrian and bicycle crashes around three university campuses in California. The crowdsource data used in this research included two sources of information: self-reported crashes as well as the perceived hazardous locations. Similar to the previous research studies, the results of the study indicated that the police records significantly underreported non-motorized crashes. The next section will discuss the impact of underreporting of crashes on crash data modeling and analysis.

Underreporting and Modeling Issues

Neglecting the underreporting issue will result in a bias sample; this bias sample induce inaccuracy in modeling, create inconsistency in classification outcomes, and result in erroneous parameter estimations. Research studies reported that both crash-frequency and crash-severity models are affected when underreporting is ignored and not considered in modeling. The underreported crash data create a biased sample that include unclear or unknown portions of the injury severities that do not represent the population ([Yamamoto et al., 2008](#)). Hence, the sample is over represented by higher severities, which can skew the estimation of parameters for some key safety variables. Underreporting will cause the threshold to distinguish injury and possible injury and the threshold to distinguish possible injury and PDO to be estimated with bias; a biased threshold consequently results in erroneous estimation of parameters or prediction of crash severities ([Hauer 2006](#)).

Crash data are often treated as outcome-based or choice-based samples instead of random samples from the population. [Ye and Lord \(2011\)](#) examined the impact of underreporting on estimation of parameters in three commonly used traffic crash severity models: multinomial logit, mixed logit, and ordered probit. They concluded that all three models are sensitive to the extent of the underreporting rate. They provided a few recommendations to minimize the bias. First, for the multinomial logit and mixed logit models, the fatal crashes are recommended to be set as the baseline severity level. Second, for the ordered probit model, the rank of the crash severity is recommended to be set from descending order from fatal to PDO. Other studies reported similar observations. For instance, research studies noted that the effect of explanatory variables could be estimated with substantial bias in severity outcome models if underreporting is not considered or ignored in modeling. A research study by [Yamamoto et al. \(2008\)](#) analyzed the impact of underreporting on ordered probit and sequential binary probit models, and concluded significant bias for both models. They also found that the bias in estimation of parameters is substantially larger when crash injuries are underreported compared to PDO crashes.

The underreporting issue was mostly studied for crash severity models; however, although it may not seem obvious initially, there is a clear need to address this issue for crash frequency models as well. Imagine a location with many minor crashes that was not reported in official statistics. This location then may not be identified as a hazardous location in hotspot identification, although it has experienced many crashes and is not considered safe. In fact, minor changes in some variables such as traffic volume or weather conditions can convert many of these minor crashes to more severe crash consequences ([Mannering and Bhat, 2014](#)). This is particularly important as in many countries the emphasis is on reduction of fatal and injury crashes (vision zero). However, if the link between minor and serious crashes is not properly defined, unsafe locations cannot properly be selected in hotspot

identification. Underreporting can also influence the number of zero observations in the dataset. As noted earlier in this article, excessive zero observations make the commonly used models such as the NB model inadequate for modeling. In addition, underreporting can lead to the low sample mean issue. When it is combined with the small sample size, this can adversely affect the parameter estimations by crash-frequency models (especially the NB model).

In short, underreporting of crash data induces significant modeling inaccuracy and should not be ignored or down played by safety researchers or practitioners. Estimating the underreporting rate might seem to be the most reliable way to handle the modeling issue with the underreported crash data. In other words, once the underreporting rate is determined or estimated, it can be applied to adjust the number of crashes. However, recall that although the sample can be adjusted when the underreporting level is properly defined, it is not easy or straightforward to assess or estimate the underreporting information in many instances—as discussed in detail in Section 3. To overcome this limitation, researchers explored other methods or techniques such as the application of adjustment estimators to alleviate the limitations imposed by underreporting of crash data. For example, Patil et al. (2012) used the weighted conditional maximum likelihood estimator to overcome the limitations imposed by an unknown underreporting rate, when statistical models such as logit or nested logit are used to analyze severity of crashes. Yet, still further research is needed to address the issue of underreporting of crash data directly or indirectly in statistical modeling of crashes.

Summary

Crash data recorded by law enforcement are considered as a crucial source of data in various stages of modeling, evaluations and analyses of highway safety. There are specific characteristics and limitations with crash data that make the data unique and the statistical analysis of crash data more challenging than a typical statistical analysis. For example, crash data may include a lot of zero observations, the sample size and the sample mean of the dataset might be small, or there might be instances that not all critical variables associated with crashes can be observed or collected. In all these cases, the typical models such as the NB model may not be adequate for modeling and the analyst may need to switch to a more advanced model to obtain better results. Most importantly, even the recording process of the crash data itself is not without limitations. In fact, one of the most critical issues with crash data modeling is related to the issue of the underreporting of crashes. While in most developed countries underreporting is rare for fatal records documented in official statistics, injury and PDO crashes are frequently underreported. Traditionally, research studies resorted to hospital data to estimate the level of underreporting in crash data. Hospital data, however, are inadequate to estimate underreporting in most instances, as hospital data itself may not be complete or can be inconsistent or may involve discrepancy with the geographical location of where the crash occurred. Recently, researchers resorted to using multiple sources of data or crowdsourcing to alleviate the inaccuracy in estimation of the underreporting rate. Yet, the accurate estimation of underreporting is a difficult task and demands significant time and resources. Safety researchers show that if not properly addressed, underreporting could result in substantial bias in estimation of parameters; consequently, the effect of independent variables might not be captured properly and can be significantly different than the reality, which will result in inaccurate safety evaluations or analyses, and incorrect investigations of the source of safety problems. Further research is needed to investigate new and modern data sources to estimate the underreporting rate, as well as exploring new methods or strategies to directly or indirectly overcome the modeling limitations associated with the underreporting of crash data.

Introduction

Utility poles are fixed objects that are intentionally placed on the roadside to carry electricity or communication wires. These objects are substantial both in sheer number and structure strength and can negatively affect the safe operation of roads. It is estimated that there are over 88 million utility poles on highway right-of-way in the United States, over 5 million utility poles in Australia, and more than 500 million utility poles in China. Most of these utility poles are made of wood, steel, or reinforced concrete. The rigid material allows the pole to have a longer service life and survive high winds of a storm and other environmental extremes, but unfortunately makes the pole unforgiving in a traffic crash. More importantly, in most countries utility poles are usually located within the highway right-of-way to avoid inference with trees and to ensure the reliability of the services carried on poles, and in some cases they are too close to the traveled lane, which makes them too dangerous to errant vehicles that run off the road and frequently leads to serious or fatal injuries.

The traffic safety problem related to utility poles, especially those not of forgiving (e.g., breakaway upon impacts) nature, has been recognized by many countries. For example, as pointed out in Transportation Research Board's *State of the Art Report 9: Utilities and Roadside Safety* (TRB, 2004), utility pole improvements have been made in the United States as early as highway engineers' recognition of the need for forgiving roadsides since the 1960s. Since then many utility poles have been removed, relocated to safer locations, or made safer in some other manner. However, there are still many more utility poles that remain in place as a significant roadside hazard in the United States. Moreover, some other countries have not paid enough attention to the utility pole crash problem. Far too many people are being killed or seriously injured each year in utility pole crashes all over the world, and many of these deaths and injuries could be avoided with appropriate safety treatments to utility poles.

This article is organized as follows. First, road safety problem related to utility poles is discussed emphasizing the fact that utility pole crashes are one of the most common fixed-object crashes and have a higher frequency of severe to fatal crashes. Contributing factors to utility pole crashes and some widely used utility pole crash prediction models are then presented. Subsequently, the importance of clear zones in reducing utility pole crashes is discussed. Last of all, safety treatments to utility poles are summarized with a discussion on their pros and cons and selection methods.

Utility Pole Crashes

A utility pole crash is the run-off-road/fixed-object crash that involves a vehicle leaving the traveled lane, encroaching the roadside, and striking a utility pole. Many people are killed and injured each year in utility pole crashes. In the United States, the proportion of fatalities involving crashes with fixed objects has remained between 21% and 23% since 2005. Among all the fixed objects, utility poles are one of the most common fixed objects to be struck, usually ranked the second after trees. The proportion of fatalities

Table 1 Fatalities of fixed-object crashes, tree crashes and utility pole crashes in the USA

Year	Fixed-object crashes		Tree crashes		Utility pole crashes	
	Number	Proportion to all crashes	Number	Proportion to fixed-object crashes	Number	Proportion to fixed-object crashes
2005	9062	21	4573	50	1223	14
2006	9181	21	4552	50	1142	12
2007	9168	22	4341	48	1191	13
2008	8661	23	4182	48	1029	12
2009	7813	23	3817	49	980	13
2010	7290	22	3614	50	1015	14
2011	7069	22	3563	50	910	13
2012	7697	23	3672	50	1004	14
2013	7553	23	3604	50	913	13
2014	7518	23	3514	47	953	13
2015	7700	22	3611	47	926	12
2016	8039	21	3801	48	897	11
2017	7833	21	3691	47	914	12

Note: The statistics are based on analysis of data from the US Department of Transportation's Fatality Analysis Reporting System (FARS).

involving utility pole crashes is between 11% and 14% of fixed-object crash fatalities and approximate 3% of total fatalities, as shown in [Table 1](#). In British Columbia and Canada, over a period of 12 years (1999–2011), the province experienced a total of 2314 crashes that involved utility poles, resulting in 68 fatalities, 1203 personal injuries, and 1043 with property damages only.

In general, utility pole crashes are not as frequent as other types of crashes. As such, highway agencies and utility companies seem to give the problem a low priority. Nonetheless, because of the high structural strength of utility poles as well as the small contact area of a collision, utility pole crashes tend to be severe. Moreover, the negative effects of utility poles go beyond the run-off-road crash type. Crashes are usually categorized by “first harmful event.” Some crashes, in which striking a utility pole is a secondary event that may be more severe than the first harmful event, are not classified as run-off-road/fixed-object crashes. A common example is that motorcycle crashes with utility poles often involve more than one impact event, and the collisions with utility poles usually have a higher fatality risk than collisions with either the ground or another motor vehicle.

Contributing Factors and Statistical Modeling

The occurrence of utility pole crashes, similar to the occurrence of other types of crashes, is influenced by traffic conditions (e.g., traffic volume, speed), road conditions (e.g., geometric alignments, pavement surface), driver characteristics (e.g., risk driving behavior, fatigue), and environmental factors (e.g., weather, lighting). Among these factors, the most important ones appear to be traffic volume, lateral offset, and pole density. Traffic volume is the exposure factor. Offset is measured laterally from the edge of the traveled lane to the utility pole. Both the crash frequency and crash severity will decrease when utility poles are placed farther away from the traveled lane. The frequency of utility pole crashes will also decrease when the number of poles along the roadway decreases, intuitively because less poles are exposed to errant vehicles. Other than the traffic volume, offset, and density, factors such as roadway class, shoulder width, horizontal curvature, intersection type, divided/undivided road, rural/urban, and speed limit are also important contributing factors.

To quantitatively measure the effects of contributing factors on utility pole crashes, several statistical models (e.g., safety performance functions) have been developed. These mathematical models are derived from crash data and are used to acquire inference on different factors that contribute to crash frequency.

The most-referenced utility pole crash model was a multiplicative model developed by ([Zegeer and Parker, 1984](#)). The model predicts the utility pole crash frequency as a function of average daily traffic (ADT, vehicle day⁻¹), pole density (Density, km⁻¹), and pole offset (Offset, m) using the linear and non-linear regression. The model is as follows:

$$\text{Crash} = \frac{(3 \times 10^{-5} \cdot \text{ADT}) + (1.735 \times 10^{-2} \cdot \text{Density})}{\text{Offset}^{0.6}} - 0.025 \quad (1)$$

The model is developed based on the data collected from four states in the United States: Michigan, North Carolina, Washington, and Colorado. Based on the available data, it is found that the model is a reasonably good predictor within the specific range of input values: ADT from 1000 to 60,000 vehicles per day, pole offsets from 0.18 to 2.77 m, and pole densities of 6–56 poles per kilometer.

In the current practice, most safety performance functions are developed with Poisson and negative binomial regression. The approach has the following theoretical basis. Let Y be the random variable that represents collision frequency at a given location during a specific time period, and let y be a certain realization of Y . The mean of Y , denoted by Λ , is itself a random

variable. For $\Lambda = \lambda$, Y is Poisson distributed with parameter λ .

$$P(Y = y | \Lambda = \lambda) = \frac{\lambda^y \cdot e^{-\lambda}}{y!} \quad (2)$$

$$E(Y | \Lambda = \lambda) = \lambda; \text{Var}(Y | \Lambda = \lambda) = \lambda \quad (3)$$

It is typical to assume that the distribution of Λ can be described by a gamma probability function with a shape parameter κ and a scale parameter κ/μ , and then the distribution of Y around $E(\Lambda) = \mu$ is a negative binomial with an expected value and variance as follows:

$$P(Y = y | \mu, \kappa) = \frac{\Gamma(y + \kappa)}{y! \Gamma(\kappa)} \cdot \left(\frac{\kappa}{\kappa + \mu} \right)^\kappa \cdot \left(\frac{\mu}{\kappa + \mu} \right)^y \quad (4)$$

$$E(Y) = \mu; \text{Var}(Y) = \frac{\mu^2}{\kappa} \quad (5)$$

Following the Poisson and negative binomial regression approach, a utility pole crash prediction model is developed by [Elesawey and Sayed \(2012\)](#), for the rural-undivided highway segments in British Columbia, Canada. The developed model includes four explanatory variables: segment length (L), traffic volume (ADT), poles density (Density), and poles offset (Offset). The final model is found to be the Poisson structure and has the following form.

$$\lambda = 0.1095 \cdot (L \cdot \text{ADT})^{0.1247} \cdot \text{Density}^{0.1162} \cdot e^{-0.905 \text{Offset}} \quad (6)$$

By setting segment length to 1.0 km, the expected utility pole crash frequency as crashes/km/year is calculated as follows:

$$\lambda = 0.1095 \cdot (\text{ADT})^{0.1247} \cdot \text{Density}^{0.1162} \cdot e^{-0.905 \text{Offset}} \quad (7)$$

Using the developed model, the percentage change of crash frequency associated with a change in the explanatory variables is estimated. It is found that the impact of density and offset on the crash frequency is more evident than the impact of the volume, and moreover increasing the pole offset has a more significant effect on reducing the frequency of utility pole crashes compared to increasing poles spacing.

Importance of the Clear Zone

The significant effect of offset on the utility pole crash frequency implies that utility poles should be placed as far as practicable from the traveled lane to provide a safe environment for traffic operation. One of the most important principles is to place the utility poles outside the clear zone. A clear zone is an unobstructed, traversable roadside area that allows an errant driver to stop safely or regain control of a vehicle that has left the roadway. Utility poles located outside the clear zone are more likely not to be struck by errant vehicles and thus collisions would be avoided.

The clear zone concept stresses the provision of wide enough roadsides free from hazards like utility poles and other ground-mounted structures. Usually, variable clear zone widths are suggested based on types of roads, speeds of vehicles, traffic volumes, horizontal curves, steepness of roadside slopes, and some other factors. For example, the *Roadside Design Guide* of the United States ([AASHTO, 2011](#)) suggests the clear zone widths of rural highways may vary from 2.0 m (for front slopes 1:4 or flatter and back slopes 1:3 or flatter, design speed ≤ 60 km h⁻¹, and annual average daily traffic (AADT) < 750 vehicle day⁻¹) to 14.0 m (for front slopes 1:4–1:5, design speed of 110 km h⁻¹, and AADT > 6000 vehicle day⁻¹) based on traffic volumes, speeds, and roadside geometry. The suggested width may be modified further with adjustment factors to account for horizontal curvature. For urban streets, although the same clear zone widths as rural highways are preferred, they are sometimes not feasible because of physical constraints. In these instances, a minimum width of 0.5 m from the face of the curb is required. The *Geometric Design Guide for Canadian Roads* of Canada ([TAC, 2017](#)) suggests the minimum clear zone widths ranging from 2.0 m (for front slopes 1:4 or flatter & back slopes 1:3 or flatter, design speed ≤ 60 km h⁻¹, and AADT < 750 vehicle day⁻¹) to 8.5 m (for front slopes 1:4 or flatter and back slopes 1:3 or flatter, design speed ≥ 110 km h⁻¹, and AADT > 6000 vehicle day⁻¹). For instances where the application of the “full” clear zone width requirements is not appropriate or cost-effective, a “reduced” clear zone by as much as 40% of the “full” width with a minimum width of 2.0 m is proposed.

Ideally no utility poles should be located within the clear zone. In practice, however, it has been difficult to satisfy this requirement due to many constraints. For road sections where it is not cost-effective to place the utility pole outside the clear zone, safety treatments as detailed in the following section may be necessary for utility poles.

Safety Treatments

Lists of countermeasures to utility poles have been provided in AASHTO’s *Roadside Design Guide* ([AASHTO, 2011](#)), and general guidelines on utility pole crash mitigation are also reiterated in Transportation Research Board’s *State of the Art Report 9: Utilities and*

Roadside Safety (TRB, 2004). This section provides a summary on these countermeasures and discusses the methods to select proper countermeasures.

Countermeasures

Keep Vehicles on the Roadway

The most obvious way to prevent utility pole crashes is to keep the vehicles on the roadway and from encroaching on roadsides. This can be realized by some low-cost, quickly implementable treatments, such as reducing speeds, installing shoulder rumble strips, installing edgeline profile marking, installing mid-lane rumble stripes, providing enhanced shoulder or in-lane delineation and marking for sharp curves, providing enhanced pavement marking, providing skid-resistant pavement surfaces, widening and/or paving shoulders, and eliminating shoulder drop-offs.

Place Utility Lines Underground

Placing utility lines underground will greatly reduce the utility pole crash potential because no poles exist unless there are streetlights along the road. In addition, this countermeasure saves the costs of removing and replacing a pole damaged in a crash and of repairing the utility lines after a crash. However, the initial cost of placing lines underground is usually very high. The full safety benefit cannot be achieved if other existing above ground structures such as transformers and switching cabinets pose a hazard to vehicles. There are also other disadvantages related to the countermeasure. For example, the underground line is vulnerable to excavation damage, the carrying capacity on underground lines is limited, and the underground line is more difficult to patrol in the case of an outage.

Relocate Utility Poles to Locations Less Likely to be Struck

Some locations are vulnerable to utility pole crashes, and an effective countermeasure is to alter the pole position to avoid these utility pole crash prone locations. A typical example of crash prone locations is the outside of horizontal curves as there are many more run-off-road crashes on the outside of horizontal curves than on the inside. Other utility pole crash prone locations as presented in *Utilities and Roadside Safety* include, the gore of highway diverging areas; downstream of a lane drop or the area where the roadway narrows; traffic islands or in the median of divided roadways; and the critical quadrants of an intersection that is intersected by two roads with significantly different speeds (TRB, 2004). An illustration of the crash prone locations to utility poles is shown in Fig. 1.

Increase Lateral Offset of Utility Poles

This countermeasure is to address the “Offset” factor in utility pole crash problems. Increasing the lateral offset of utility poles is an attractive countermeasure, since both the frequency and severity of utility pole crashes will decrease when poles are moved farther away from the roadway. Ideally, utility poles should be placed at the right-of-way line and outside the clear zone. This means the lateral offset should be at least 2.0 m from the edge of the traveled lane of rural highways and 0.5 m from the face of curb of urban streets.

Practically, the right-of-way is usually expensive to acquire and not always available, which makes this countermeasure heavily site dependent. As well, the full safety benefit of the countermeasure cannot be achieved if other fixed objects remain in the clear zone.

Decrease the Number of Utility Poles

The countermeasure is to address the “Density” factor in utility pole crash problems. Decreasing the number of poles along a road section indicates fewer obstructions that are less frequently being struck and larger openings that allow a vehicle to pass through. If there is a wide enough recovery area behind the poles, the larger openings allow a vehicle more space to recover.

There are several methods to decrease the number of utility poles along a roadway. For example, encouraging the joint use of existing poles, with one pole carrying electric power, telephone, and other utility lines; placing poles on only one side of the road; increasing pole spacing by extending span lengths for utility poles. Increasing the pole spacing or placing poles on one side of the road may require using larger poles. These larger poles, however, may cause an increase in the severity of crashes because of their larger size.

Use Breakaway or Energy Absorbing Poles

To use breakaway or energy absorbing poles is an alternative treatment for utility poles that have to remain in place. Both types of poles are directed at reducing the severity of utility pole crashes. However, they are different in operating principles. Breakaway poles are designed to break away upon impact and swing out of the path of the vehicle. Energy absorbing poles are designed to “capture” the vehicle and stop it gently enough so that velocity change and deceleration do not exceed requirements established for the safety of a vehicle’s occupants.

The breakaway design has shown its effectiveness in reducing crash severity in sign supports and luminaire supports, and it has also been applied to utility poles and proved to be effective in some countries. However, unlike the signs and luminaires, a utility pole is not an isolated element, and there is concern regarding the “domino effect” of a single weak pole causing many poles to fall. Considering that the final position of the pole and conductors (wires) may create hazard for pedestrians, the breakaway pole is also not suggested in an area of significant pedestrian activity such as an urban area. Instead, the energy absorbing poles that can

Figure 1 Utility pole crash prone locations.

“capture” the vehicle and stop it from encroaching the pedestrian area or hitting other road hazards are preferred. The problem with the energy absorbing poles is that they can entrap the vehicle at high speeds causing yaw, which overturns the vehicle and results in serious bodily harm.

Shield Utility Poles With Safety Devices

For utility poles that cannot be removed or placed underground, a potential countermeasure is to shield them with safety devices, such as roadside barriers and crash cushions. A roadside barrier is a longitudinal system used to shield vehicles from natural or man-made hazards along the roadway, and widely used barriers include low profile barrier and W-beam guardrails. A crash cushion functions by collapsing upon impact and slowing the vehicle at a controlled rate, and examples include sand or water filled containers.

Using safety devices to shield utility poles can only reduce the severity of crashes, and it is usually considered after removal or relocation has been ruled out. An important reason is that the installation of these devices increases the probability of a crash occurring, by exposing a larger area to the errant vehicle, and being closer to the roadway than the protected utility poles. In addition, there are some instances in which installing safety devices are not appropriate. A common example is that there is not enough room between the utility pole and the traveled lane to allow the safety device working functionally.

Delineate Utility Poles in Hazard Locations

Another countermeasure for utility poles in hazardous locations is to make them more visible, and thus errant drivers are alerted to the presence of utility poles and may take necessary evasive actions if the vehicles are under some level of control. However, if the vehicle is out of control, the safety benefits of pole delineation would be minimal. The delineation can be done with reflective paint, sheeting, object markers placed on utility poles, and roadway lighting.

A major problem with this countermeasure is that its low cost may make it appear attractive. However, the effectiveness is questionable, and there may not be any real safety improvement after the treatment. Therefore, this countermeasure should be only considered when all other options are exhausted.

Countermeasure Selection

The aforementioned countermeasures have their pros and cons, and there is not such a one-fits-all countermeasure. Countermeasures should be selected depending on local conditions, size of the program, funds available, and other factors. The selection may be made through the judgment of an informed individual or a group of individuals, and the best way for selecting countermeasures is to perform a cost-effectiveness (or cost-benefit) analysis.

The cost-effectiveness evaluation involves comparing the costs of various countermeasures to determine the most effective use of limited funding. Costs include potential future crashes, initial construction costs, ongoing maintenance costs, and similar items. Benefits include a reduction in the number of crashes, reduced maintenance costs, and the salvage value of the facility at the end of useful service life. Most importantly, the reduction in the number of crashes is estimated based on safety performance functions of utility poles, as shown in Eqs. (1) and (7). Benefits and costs are compared to determine whether an improvement is cost-effective and to set priorities among different countermeasures or their combinations competing for limited funds. It is noted that the comparison should consider the period of time in which each countermeasure provides a benefit and thus costs and benefits should be annualized using discount rates. Examples of detailed cost-effectiveness analysis procedures can be found in the *Roadside Design Guide* (AASHTO, 2011).

Summary

Utility poles, which are placed near the road substantially affect the safe operation of roads because of their large number and high structural strength. Vehicles that run off the road and strike a utility pole tend to suffer large deformation, which frequently leads to serious or fatal injuries. Statistics have shown that utility poles are one of the most common fixed object struck among all the fixed objects.

The occurrence of utility pole crashes are influenced by many contributing factors, and among them traffic volume, speed, lateral offset, and pole density are the most prevalent ones. Different statistical models are developed to relate utility pole crashes to these significant contributing factors. This article summarized the most widely used multiplicative model developed in 1984 and the safety performance function developed with the state-of-the-practice Poisson and negative binomial regression methods. The latter model also shows that the impact of density and offset on the crash frequency is more evident than the impact of the volume, and moreover increasing the pole offset has a more significant effect on reducing the frequency of utility pole crashes compared to increasing pole spacing. This finding suggests the importance of placing the utility poles outside the clear zone.

A comprehensive group of safety treatments for utility poles is summarized at last. These include countermeasures as following: keeping vehicles on the roadway, placing utility lines underground, relocating utility poles to locations less likely to be struck, increasing lateral offset of utility poles, decreasing the number of utility poles, using breakaway or energy absorbing poles, shielding utility poles with safety devices, and delineating utility poles in hazard locations. These countermeasures have their pros and cons, and they should be applied after a thorough consideration on local conditions, size of the program, funds available, and other factors. The cost-effectiveness analysis is suggested to aid the treatment selection.

Introduction

One important conceptual advance in the state of practice of road safety valuation was achieved in the 1980s by valuing road safety according to subjective preferences rather than by using the heavily criticized *human capital* (HC) *approach*. The HC rests on accounting principles: the benefit of avoiding a premature death is given by the present value of the income flow the economy could lose in that case. More appropriately, the *value of risk reductions* (VRR)—initially known as the *value of a statistical life* (VSL)—is based on subjective preferences and given by the amount of money that individuals are willing to pay for reducing the risk of their premature death while performing a certain risky activity. The focus on the VRR in contrast to the HC value yields higher benefits for risk avoidance, and hence the social net benefit of safety policy measures has increased in recent years, prompting many road safety interventions, otherwise not socially profitable, in the developed world (Viscusi et al., 1991).

The VRR for road contexts was estimated originally using contingent valuation (CV), standard gamble, or the chain method (Schwab and Soguel, 1995; Hausman, 1993), but the approach, in general, was heavily criticized by specialists in human behavior and economics. In original studies, people were confronted with situations expressing risk as tiny probabilities, and needing a trade-off between risk and money to arrive at a monetary value (Some of these studies posed a risk–risk trade-off. However, in order to arrive to a monetary value a risk–money trade-off is necessary, sooner or later). This kind of simulated context may not bear upon actual choices on route selection or travel behavior in general, where individuals have to consider a bundle of attributes describing each alternative (i.e., travel time, toll, and safety in a route choice context).

Some authors have proposed a different approach based on stated choice (SC) techniques (Rizzi and Ortúzar, 2003; Hensher et al., 2009; Iragüen and Ortúzar, 2004). In an SC survey, individuals are asked to choose among different alternatives, the attribute levels of which vary according to a statistical design aimed at maximizing the precision of the estimates; as such, SC allows the analyst to mimic actual choices with a relatively high degree of realism, and for this reason most experts believe that it is an appropriate elicitation method for the valuation of intangibles (Louviere et al., 2000).

The Value of Fatal Risk Reductions in a Road Safety Context

To understand the interpretation of the willingness to pay (WTP) for the safety attributes, it is useful to provide some theoretical background to the meaning of the evidence. We focus on a road setting. Assume a route, used by N users. If person n travels more than once in a reference period, say m_n times, this gives rise to m_n pseudo-members with a total population of $N = \sum_{n=1}^N m_n$, observations, that is, the individuals of a population. This population exactly amounts to the flow on a route in a given period (say a year). Bear in mind though that a population is a stock variable whereas a flow is not. A route is defined as a path connecting one origin–destination (O–D) pair. A trip on a route provides a level of dissatisfaction (or disutility) given by a deterministic indirect utility function $V = V(r, c, t)$, where r stands for risk of a fatal crash or class of injury, c for the cost of travel, and t for the travel time (mean and variability) on a route; there could be more attributes, of course.

Focusing only on fatality, we can formally define VRR as the value of avoiding one expected death, and this corresponds to the population (or sample) average of the marginal rate of substitution (also known as WTP) between income and risk of death for person n (MRS_n) plus a covariance term that accounts for possible correlation between MRS and reduced risk (δr_n):

$$MRS_n = \frac{\partial V_n / \partial r}{\partial V_n / \partial c |_{V=\bar{V}}} \quad (1)$$

$$VRR = \frac{1}{N} \sum_{n=1}^N MRS_n + N \text{cov}(MRS_n, |\delta r_n|) \quad (2)$$

where $\text{cov}(MRS_n, \delta r_n) = \sum_n MRS_n \delta r_n - \frac{1}{N} \sum_n MRS_n \frac{1}{N} \sum_n \delta r_n$

In empirical work, it is typically assumed that there is no correlation between WTP and δr in the population. Then, Eq. (2) simplifies to Eq. (3), and to estimate the VRR, it is sufficient to have a good estimate of the MRS (or WTP). This assumption would be correct, for example, if δr is the same for every individual.

$$VRR = \frac{1}{N} \sum_{n=1}^N MRS_n \quad (3)$$

The MRS can be interpreted as an implicit value for the traveler's own life, and averaging it over all individuals traveling on the route yields the VRR. The MRS clearly depends on personal risk perceptions according to the functional form of V_n . The same analysis can be carried out in terms of fatal crashes, f , (or injuries), instead of risks, r . However, in this case, the VRR is derived differently (but yields the same value):

$$VRR = \frac{1}{e} \sum_{n=1}^N \frac{\partial V_n / \partial f}{\partial V_n / \partial c |_{V=\bar{V}}} = \frac{1}{e} \sum_{n=1}^N SVCR_n \quad (4)$$

where e represents the number of fatalities or injuries (by class) per crash (effectively the information that relates to exposure to risk) and SVCR stands for the subjective value of fatal crash injury (by class) reductions, and is a Lindahl price. Eq. (4) embodies the definition of community WTP for a public good, road safety in this case, as the sum of individual marginal rates of substitution between income and number of fatalities and injuries (by class).

As a context example, if it is thought of in terms of a hypothetical tolled route, whose operators were able to extract the full consumer's surplus, the SVCR would be the maximum toll increase due to a safety improvement for individual n , such that they are as well-off as before the improvement. If the VRR is higher than the cost of reducing one fatality or one injury (by class), the safety project should be desirable from the community standpoint; in what follows it will be assumed that e is equal to one.

It can be seen that one advantage of dealing with the variable number of fatal or injury crashes, rather than risk, in empirical work. From Eqs. (2) and (4), it follows that

$$VRR = \sum_{n=1}^N SVCR_n = \frac{1}{N} \sum_{n=1}^N MRS_n + N \text{cov}(MRS_n, |\delta r_n|) \quad (5)$$

In other words, estimating the SVCR and aggregating across individuals will yield the correct VRR irrespective of the value of the covariance and this follows from the definition of our public good; one statistical death (or injury class reduction) reduction (per unit of time) on a particular route. (A statistical death reduction means saving one life, on average, per unit of time (obviously whose life is saved is unknown). This suggests that to elicit the VRR, rather than asking people to place a value on risk reductions, they should be asked to value a reduction in fatal or injury class crashes; it is believed this task is far easier from the respondents' standpoint. The two approaches are mutually consistent only when respondents have the correct aggregate flow in mind (i.e., they would value an extra fatal or serious injury crash per year different if they were to make the only trip on that road that year, than when millions of trips would be made on that road). In this sense, although a formulation in terms of number of crashes may sound more natural and easy-to-understand than a formulation in terms of probabilities to most respondents, the cognitive burden may not become any lighter. This is the basis of the popular WTP approach and reflected in the outputs derived from a discrete choice model.

Making the Model Operational

The model can be made operational within a (binary) discrete choice framework where the indirect deterministic utility of each available alternative j is

$$V_j = \alpha f_j + \eta \text{MajI}_j + \theta \text{MinI}_j + \phi \text{IncapI}_j + \beta c_j + \gamma \text{meant}_j + \lambda \text{stdev}_j + \text{other influences } (j = 1, 2) \quad (6)$$

where f is the number of fatalities, MajI is the number of major injuries, IncapI is number of incapacitating injuries, MinI is the number of minor injuries, t is trip time, and c is trip cost. The SVCR is equal to α/β for fatalities for every individual, η/β for major injuries, θ/β for minor injuries, and ϕ/β for incapacitated injuries for every individual. The definition of injury and its classification tends to vary by the geographical jurisdiction and is often in disagreement.

Also note that by computing γ/β , the behavioral value of travel time savings (VTTS) is obtained and λ/β is the value of reliability (VoR), two other useful outputs that relate to trading of the features of a trip setting. This model form is couched in the context of a specific trip context where travelers face travel times, travel costs, and safety of the road environment (defined by a history of deaths and injuries). By varying the levels associated with different travel contexts, a rich array of data can be gathered that is the basis of identifying traveler preferences for each of attributes being investigated. Simply put, the variability in an attribute level within a package of trips provides the necessary data to reveal, through choice model estimation, the contribution of each attribute (i.e., its marginal utility or disutility) to overall utility which is the representation of preferences. By comparing the marginal (dis)utility of an attribute of interest (e.g., travel time) to the marginal (dis)utility of cost an estimate of a WTP for a unit of the attribute of interest in dollars can be obtained.

For safety, the estimation of the choice model (Hensher et al., 2015) provides parameters for the safety attributes that are used to obtain the WTP to avoid a fatality or a class of injury in a road environment. To allow for preference heterogeneity, the number of deaths and injuries by category can be estimated with random coefficients. As the modeler does not possess all the relevant information, he must assume randomness in the utility function. Random utility, U , is simply expressed as the sum of two terms: deterministic utility, V , and a random component ε :

$$U_i = V_i + \varepsilon_i \quad (7)$$

It is assumed that each alternative i has a probability of being chosen, given by the probability that U_i is the highest random utility. A useful extension of Eq. (7) is to parameterize indirect utility according to socio-economic (SE) variables in order to attain what can be called as deterministic taste variations:

$$V_{ij} = \left(\alpha + \sum_l \alpha_l s_{lj} \right) f_{ij} + \beta c_{ij} + \lambda t_{ij} \quad (i = 1, 2) \quad (8)$$

where the binary variable s_{lj} represent the SE characteristic l of individual j , and i is the choice alternative (All level-of-service parameters can be tested for systematic variations in this form.). This is an interesting way of incorporating SE variables; with the advantage that if the information is used to estimate the SVCR, say, Eq. (8) states that there may be different coefficients for each attribute depending on the characteristics of the individual.

If the random terms are identically and independently Gumbel distributed (iid) between alternatives and across individuals, the popular multinomial logit (MNL) model is obtained and the probability of choosing alternative i is given by:

$$Prob(i) = \frac{\exp(\lambda V_i)}{\sum_{m=1,2} \exp(\lambda V_m)} \quad (9)$$

where λ is a scale factor inversely related to the unknown standard deviation of ε , and in practice has to be normalized to one as it is not identifiable (Hensher et al., 2015).

The MNL is not capable of addressing the issue that many responses may be provided by each individual in the SC case. We need a more powerful model that allows correlation among the choices made by the same person. The mixed logit model allows not only to do that, but also to consider random parameters. The mixed logit (ML) choice probabilities consist of a logit kernel that has to be integrated over the distribution of taste parameters:

$$Prob(i) = \int \frac{\exp(V_i)}{\sum_{m=1,2} \exp(V_m)} f(\alpha, \beta, \gamma | \Xi) d\alpha d\beta d\gamma \quad (10)$$

where $f(\bullet)$ represents the joint distribution of the parameters α , β and γ , and Ξ , the (usually unknown) population parameters that characterize the distribution.

Aggregating Individual WTP to the Population

The overall value for safety improvements (public goods) is a summation of individual WTP (WTP_i). The resultant figure is a reflection of what the safety improvement is “worth” to the affected group, relative to the alternative ways in which each individual might have spent his or her limited income. Research supports the WTP approach to the valuation of safety to determine the maximum amounts that those *affected* would individually be willing to pay for (typically small) improvements in their own and others’ safety.

For car drivers, the WTP is the vehicle driver’s marginal rate of substitution between income and number of annual road fatalities or number of serious injuries; and VRR is the summation of WTP (*separately for fatalities and serious injuries on a specific route*) over all drivers that traverse a specific road in a given year. Summing WTP values over all drivers (annual flow) on each route, we obtain two values—the societal value of fatality risk reductions (VF) and the societal value of serious injury risk reductions, that is, value of a severe injury (VSI). Note that the sources of societal aggregate WTP are many and varied. These include users’ WTP (including altruism if it exists) and nonusers WTP; with respect to the latter we would only count altruism (in the sense of taking care of others’ road safety). The WTP of nonusers is unlikely to be the same as users’ WTP (which includes the self-interest value). You cannot scale to the whole population from a subpopulation. To capture WTP of non-road users, one should consider a survey on nonusers to infer their WTP. Thus, multiplying drivers’ WTP by the total population rather than by the drivers’ population will overestimate the WTP for his segment.

With a focus on specific car trips, we have to convert the individual WTP to a *driver population exposure risk measure*. The traditional method based on the HC approach simply took the aggregate cost associated with all fatalities and serious injuries and paid no attention to the risk spectrum in which the cost of HC was linked. This link is critical to the validity of the societal WTP and cannot be disassociated from the specific level of risk associated with each trip.

The *exposure* of interest is reflected in the number of trips and associated kilometers undertaken by each driver in the population. The trip kilometers associated with driving have to be expanded up to the relevant population based on the number of times an individual in a subpopulation is exposed to risk. Identifying the actual amount of trip activity is crucial in aggregating up the average WTP per trip. The formulae for inputting the calculations for each risk class are:

$$\begin{aligned}\text{Societal } VRR_{rnf} (= VSL_{rnf}) &= \text{Societal } VF_r; r = \text{regions } 1, 2, \dots, R. \\ \text{Societal } VRR_{rvi} (= VSL_{rvi}) &= \text{Societal } VSI_r; r = \text{regions } 1, 2, \dots, R.\end{aligned}$$

The components of the calculation of the Societal VRR can be defined simply as WTP/chance , where *chance* is defined by the relationship between the *risk* as measured by the number of fatalities per annum or number of serious injuries per annum and *exposure* is defined by the annual number of vehicle kilometers.

$$\text{Societal } VF = \frac{\overline{WTP \text{ per trip}_r}}{\overline{\text{Trip kilometers}_r}} \times \frac{AAVKM_r \times 365}{\# \text{ fatalities}_r} \quad (11)$$

$$\text{Societal } VSI = \frac{\overline{WTP \text{ per trip}_r}}{\overline{\text{Trip kilometers}_r}} \times \frac{AAVKM_r \times 365}{SI_r} \quad (12)$$

WTP is an average or median WTP per person per trip; the average number of fatalities or severe injuries is an average over a period, such as the last three 3–5 years; and the average annual daily vehicle kilometers (AAVKM), is also over the same period. The reason for 3–5 years is because accidents are very random in nature, so it is good to have averages over such a period of years. That figure would be more stable than the number in one specific year.

To illustrate how this formula will work, let us assume a representative driver WTP (averaged over all drivers in the sample in the r th region) of \$0.20 per vehicle kilometer. Let us assume from our population data in the r th region that the chance of death per annum associated with driving a car is three fatalities divided by 6,000,000-vehicle kilometers per annum. The VSL is the WTP of the representative car-driving trip divided by the chance of death. This is $\$2 \div [3/6,000,000] = \$400,000$. This is the sum that society would be willing to pay to reduce the risk by one statistical death.

One major challenge is in how to work with a road network where the risks vary quite substantially across the network, within each region. That is, where the ratio of accidents to flow or exposure per route differs. There are two main options: (1) to work with each route safety record, or (2) to group routes according to some characteristic and work with their aggregated road safety record (for example, route A: 1 death per year; flow, 2,000,000; route B: 2 death per year; flow 3,500,000; and aggregated: 3 death per 5,500,000 flow). In the latter situation, if routes are of different lengths, it may be necessary to standardize in terms of deaths and serious injuries per million vehicle-kilometers.

We suggest that a way forward for car drivers is to sample representative routes and obtain data on annual trip kilometers (based on number of trips and average distance if trip kilometers are not readily available) and accident record (road vehicle fatalities and serious injuries). As long as we have information on the amount of traffic on these roads, compared to the entire eligible regional network, we can use this data on exposure (annual vehicle kilometers) and risk (aggregated fatalities and serious injuries) to obtain the chance indicator for Eqs. (11) and (12).

Where we have different routes for different O–D trips, everything will work fine as per the text. But if you have a link as part of a route for different O–D trips, you will also have to know the proportion of trips for each O–D, because vehicle kilometers will differ. For example you have Route 5 joining Taree–Sydney–Wollongong. Someone going from Taree to Wollongong will traverse the link Taree–Sydney, so on that stretch of the road all drivers (whether they go to Sydney, Wollongong, or further south) will be exposed the same travel time and road safety conditions, but the individual when choosing her preferred route will see what each alternative route offers to accomplish the trip. So to expand, you need know the proportion of trips corresponding to each O–D, to be able to establish a WTP measure per kilometer. As long as you know that proportion, the methodology will work fine. An O–D matrix with its corresponding traffic assignment available from any past study would be useful.

Altruistic Versus Individual Values

Altruism is only valid to be counted if an individual's utility is a function of other people's safety $U = U(\dots; \text{others' safety})$, not if it is a function of other people's welfare $U = U(\dots; \text{other's } U)$. To the extent that people display "altruistic" concern (people's WTP for others' safety as well as their own) then *prima facie* one would expect that it would be appropriate to augment the WTP-based VSL and VSI to reflect the amounts that people would be willing to pay for an improvement in others' safety.

However, under some simple assumptions regarding the nature of people's altruistic concern for others' safety on the one hand and their material well-being on the other (the latter being reflected by their wealth or consumption), augmenting the VSL and/or VSI to reflect WTP for other's safety would involve a *form of double-counting* and "would therefore ultimately be unwarranted."

In Chilean surveys, it was found that if someone travels with someone else, his or her WTP is higher than that of someone traveling alone. It was also found that WTP was affected by whether the driver has children (independently of whether they are

traveling with children or not). Those two factors are important to control for because otherwise one could think of altruism when actually it is not present. Of course, for many drivers other passengers could be their children.

Concluding Comments

There is growing support for the WTP approach with an emphasis on ex ante identification of VRR in contrast to the ex post HC measure. In addition, there is support for assessing road safety benefits in the context of real travel settings such that we can identify the trade-offs being made between all of the attributes influencing specific trip-related decisions. The VRR studies find that the VRR associated with a fatality in western economies are in the range of \$US8–\$15 m. The evidence on VRR for various human injury classes (e.g., minor, serious, incapacitated) vary a great deal and appear to be typically in a range of \$US200,000–\$US1.5 m. There remains controversy on the definitions of injury classes and measurement of exposure (defined in terms of kilometers of travel and history of actual injury levels in various geographical jurisdictions).

Introduction

Urban Transportation Systems (UTSs) are the lifeblood of cities, supporting mobility of millions of people and providing the means for exchange of goods and connecting businesses. As they underpin the global supply chain, the efficient and sustainable performance of these systems is crucial in all urban, rural, and in-between spaces, particularly for emergency management (e.g., evacuation, rescue, and recovery).

UTSs are under increasing pressure from two fronts. First, due to mass in migration into cities, UTSs are under increasing overcrowding and use-related deterioration. Second, the impacts from weather-related hazards (like heavy rainfalls, flash floods, etc.) are likely to increase due to climate and socioeconomic changes. These hazards are especially disruptive for transportation systems, both at a financial and a societal level; for instance, Hurricane Sandy caused \$7.5 billion of damages to New York City's transportation system of New York City, while immobilizing access for millions of users.

Considering the magnitude of societal debilitation that these events can cause to cities, understanding the resilience of UTSs is one of the most important missions of local, national, and international governing bodies (Schweighofer et al., 2014). A resilient and safe transportation system aims to efficiently respond to gradual and sudden environmental changes, as well as adapt to emerging technologies in the fields of transportation, data science, climatology, and meteorology.

Transport is a challenging sector in the context of climate impact modeling because its components have unique vulnerabilities to changes in climate system, which may cause their failure or impairment (Faturechi and Miller-Hooks, 2014). Such components can respond to weather differently according to the spatial and temporal scale (Pregnolato et al., 2019). In addition, the answer of the components is not independent since UTSs are related by many interdependencies. In other words, a failure in one component can cause cascading failures that could be inter-sectoral. The interlinked nature of UTSs means that impacts in one location can affect other areas in various period of time.

Chapter Scope

The focus of this chapter is on safety of UTSs. In particular, the content was tailored to provide insights into the state-of-the-art regarding road transport performance in adverse weather conditions. After a general overview of all major impacts to UTSs due to natural and man-made hazards, the chapter emphasizes how roadway conditions are influenced by a variety of adverse weather events (e.g., snow, rain, heat, and windstorm) in terms of safety, service delivery, and accessibility. This chapter also provides the thresholds of adverse weather events that can impact roadway conditions in different countries around the world to give the readers a better understanding of geographical location importance in the context of road safety.

The chapter sections are: (1) an overview of the latest understanding on weather impact on transportation networks, specifically road systems; (2) overview of the modeling technique used in road transport sector and technological gains that improve how these models impact the study of these networks; (3) case studies of technological use in practical application. This chapter will also introduce new approaches and identifying challenges within transportation networks, putting them in the wider context of traditional approaches to study these systems. The topic is discussed by underlining multi-disciplinary cross-cutting issues to invite the reader to personal reflection and creative thinking.

Key Definitions

In recent years, transport resilience has turned into a rapidly growing topic with extensive specialized literature. The key definitions detailed below are used in the realm of transport resilience study (and beyond). It is worth noting that some of these terms have overlaps and interchangeable meanings depending on the projects and preferences of research scholars. Authors may differ in the use of terms; therefore, the definitions below represent the specific use of terminology in this chapter.

Risk. Combination of hazard, exposure, and vulnerability; it measures the likelihood of occurrence of an event, and the consequences on the object at risk.

Hazard. Natural or man-made event that threatens objects of interest, causing perturbation or disruption of its physicality and/or functionality. It is measured by specific parameters (intensity measures) and probability of occurrence (frequency). Usually its location, impact area, and severity cannot be predicted with certainty.

Exposure. Inventory of the objects of interest, including information, such as location, material, age, etc. It represents objective information, independent from the hazard considered. Such information is usually stored in (geo-)databases.

Vulnerability. It measures the object susceptibility to a certain hazard, given the exposure characteristics. It is usually expressed by damage (vulnerability or fragility) curves that express the negative consequences due to the impact.

Resilience. It is defined as the system's ability to resist and absorb the negative consequence due to a hazard. This includes potential adaptation or mitigation measures to support the persistence of the performance in non-favorable conditions.

Recovery. Post-event actions to restore functionality at (at least) pre-event levels. The cost and time of recovery are important parameters when planning and prioritizing those actions.

Serviceability. State or condition under which an asset is considered useful. The level of serviceability refers to the performance of the asset, from full service (100%) to non-serviceability (0%).

Method

UTSs consist of a range of different modes, namely water, road network, railway, and air (Fig. 1). All of these networks are vulnerable to a range of natural and man-made hazards that can be categorized into four main groups (Faturechi and Miller-Hooks, 2014):

1. Natural weather events (e.g., rain, flood, wind gust, heat, and snowfall)
2. Natural geological events (e.g., earthquakes, volcano ashes, tsunamis, and hurricanes)

Figure 1 The range of different modes of the urban transportation system; this chapter focuses on road systems impacted by adverse weather events.

3. Operational and technological mistakes (e.g., hardware breakdown)
4. Malicious attacks (e.g., terrorism)

The risk from natural hazards encompasses the hazard characteristics (in both intensity and frequency), the asset exposure to that special hazard, and its vulnerability to that specific event (Grossi et al., 2005).

The vulnerability of the infrastructure asset depends on a series of factors (Pregnotato et al., 2016; Kermanshah et al., 2017): (1) the role of the links in the network (measurable by e.g., graph theory); (2) the exposure to the hazard; and (3) the number of users who rely on the asset. Identifying the areas with higher likelihood of hazard occurrence and higher consequences is fundamental for risk management. Such “hotspot” identification provides strategic information regarding urban dynamics and urban planning, which can be used to select critical links and target adaptation options. When dealing with infrastructure adaptation work, resources are limited, and prioritization is crucial. Within the network system, the degree to which the reduced performance of a link or node will impact the overall functioning of the network is called network criticality. This helps identify which network sections are likely to have large-scale impacts for society and economy, and thus are of critical importance to inform cost-effective adaptation strategies.

Within the context of road safety, adverse weather conditions are to be seen from the operational perspective as “atmospheric conditions unfavorable to optimal traffic conditions” (Schweighofer et al., 2014). Adverse weather events can cause direct and indirect damages to networks. Direct damages are those related to physical losses (e.g., damage to road surface); indirect damages relate to the loss of functionality, such as business interruption, service disruption, and lack of accessibility. The latter have a wider spatial and temporal scale, and are potentially more costly than the direct losses. Functional measures assess the effectiveness of a network (i.e., performance of the provided service) when it serves the community. More specifically, functional measures focus on serviceability of the transportation system, including travel time/distance, flow, and accessibility.

The journey time is usually considered the key output measure to assess the performance of a transport network, and transport modeling enables the estimation of travel times across a network (Pregnotato et al., 2016). Specifically, the (indirect) economic cost of the weather impact consists of estimating the delays in the traveling time of users, converted into monetary terms using the average value of time (VoT). The users’ VoT depends on many factors, such as the trip type (e.g., leisure/working), traveling conditions (e.g., mean, class), and the location (e.g., country, urban/rural). This appraisal could also include other metrics and quantify additional impacts, such as the increase in air pollution due to vehicle emission, or social impacts in terms of driver health and well-being. However, the appraisal of these metrics is difficult to be captured in economic terms. Certainly, more inclusive and refined calculations would imply extra complexities in the modeling. The complex nature of transport (and wider infrastructure networks) is typical for most developed countries, and implies unique demands for modeling and analysis.

Impact of Adverse Weather Events to Roads

Precipitation, rain and snow, and ice represent the biggest risks of disruption due to slipperiness, loss of visibility, or vehicles maneuverability reduction (Schweighofer et al., 2014). High winds can cause significant disruption by blowing over vulnerable vehicles (e.g., high-sided vehicles, motorbikes, and caravans) and trees. Flooding is another major cause of disruption, resulting in partial or total closure of lanes. Fog is hazardous to traffic since it reduces visibility and increases the risk of vehicle accidents and congestion. High temperature does not usually cause disruption to roads; however extended hot periods can lead to uneven road surface (due to thermal expansion), which require repairs, and may lead to indirect damages due to roadworks. In the period 2010–13 in the United Kingdom, approximately 60% of highway disruptions were related to high wind speeds, and approximately 40% were related to flooding; at local level, flooding is the most widespread problem, since disruption can last several days. Between 1996 and 2010, six US states, experienced increased rates of car crashes and injuries at a rate of 10% and 8%, respectively during rainfall days. These numbers increased to 51% and 38% during days that had over 50 mm of rainfall.

As a practical approach, precautionary road closures can be implemented to avoid incidents. Various agencies have different regulations, but their decisions are usually based on expert judgment and thresholds. Thresholds define the upper limit of the level of service a network can guarantee while preserving safety. Through review of available literature (e.g., Schweighofer et al., 2014), a series of thresholds for adverse weather events impacting roads are proposed in Table 1, for the European Union, Japan, and the United States of America.

These thresholds closely relate to the geographical location and are sensitive to individual contexts; therefore, they are not fixed values and might differ from place to place. As a result, different countries developed their own standard. For example, considering the same amount of rainfall, Japan tends to set the speed reduction to be higher than other countries, since the country regards safety as the highest priority. We can see also that Japan has no concern on the ice temperature. According to the geographic location of the country, most areas in Japan rarely face a winter as bitter as -20°C . This is different in the United States where each state has totally different climate standards, due to the size of the country; hence determining common temperature thresholds is not possible. Generally, many US cities are susceptible to other natural hazards, such as hurricanes, storm surges from hurricanes, and sea level rise. Each of these natural hazards can have different impacts (e.g., sea level rise does not have instantaneous impacts) in different cities. For example, Miami (Florida) is likely to be the worst-affected city in North America, according to the latest climate change projections (more than 3°C temperature increase by 2100) happen, which will cause the city to be totally submerged; moreover, the barrier islands and geology is such that seawalls cannot be built in an effective way (e.g., as for New York). Hence, the country focuses more on adaptive policies and how to set standards on when to evacuate.

Table 1 Thresholds for adverse weather events for several areas (EU, Japan, and United States)

Hazard	EU		Japan		USA	
	Threshold	Impact	Threshold	Impact	Threshold	Impact
Rainfall (RF)	$0.16 \leq \text{RF} < 6.4 \text{ mm h}^{-1}$	Light rain, speed reduction range 4%–10%	$\text{RF} < 15 \text{ mm h}^{-1}$	Light rain, recommended speed 80 km h^{-1} .	$0.25 \leq \text{RF} < 6.35 \text{ mm h}^{-1}$	Light rain, speed reduction range 2%–14%, reductions in capacity 0%–15%
	$\text{RF} \geq \text{mm h}^{-1}$	Heavy rain, speed reduction range 10%–30%	$15 \leq \text{RF} \leq 20 \text{ mm h}^{-1}$	Heavy rain, recommended speed $60\text{--}70 \text{ km h}^{-1}$ Very heavy rain, recommended speed 60 km h^{-1} .	$\text{RF} \geq 6.35 \text{ mm h}^{-1}$	Heavy rain, speed reduction range 5%–17%, reductions in capacity 0%–15%
Snowfall (SN)	$10 \leq \text{SF} < 100 \text{ mm in 24 h}$	Slipperiness, increased car accident rate	$\text{RF} > 20 \text{ mm h}^{-1}$		$1.5 \leq \text{SF} < 12.7 \text{ mm h}^{-1}$	Light/moderate snow, speed reduction range 3%–10%, reductions in capacity 5%–10%
	$100 \leq \text{SF} < 200 \text{ mm in 24 h}$	Reduced friction, double car accident rate and delays	$\text{SF} \geq 10 \text{ mm}$	Slipperiness and increased accident rate.	$\text{SF} \geq 12.7 \text{ mm h}^{-1}$	Heavy snow, speed reduction range 20%–35%, reductions in capacity 25%–35%
	$\text{SF} \geq 200 \text{ mm in 24 h}$	Snow accumulation, road closed				
Ice (T as mean Temperature)	$-7^{\circ}\text{C} < \text{T} \leq 0^{\circ}\text{C}$	Ice formation, increased accident risk	na	na	na	na
	$-20^{\circ}\text{C} < \text{T} \leq -7^{\circ}\text{C}$	Reduced effect of salting, delays, increased car accidents				
Flooding (FD as Flood Depth)	$\text{T} \leq -20^{\circ}\text{C}$	Fuel problems, slipperiness				
	$0 \leq \text{FD} < 50 \text{ mm}$	Reduced speed	$0 < \text{FD} \leq 100 \text{ mm}$	Normal condition	na	na
	$5 \leq \text{FD} < 300 \text{ mm}$	Reduced speed, delays, congestion	$100 < \text{FD} \leq 300 \text{ mm}$	Reduced braking performance		
	$\text{FD} \geq 300 \text{ mm}$	Unsafe driving conditions, roads closed	$300 < \text{FD} \leq 500 \text{ mm}$	Engines stop, closed roads		
Wind Gust (WG)	$17 \geq \text{WG} > 25 \text{ m s}^{-1}$	Trees can fall onto roads	$\text{FD} \geq 500 \text{ mm}$	High danger	Wind gusts $\geq 20 \text{ m s}^{-1}$ in 36 h	Wind advisory: Unsecured objects may be blown around and reduced visibility
	$25 \geq \text{WG} > 32 \text{ m s}^{-1}$	Reduced visibility, fallen trees	$15\text{--}25 \text{ m s}^{-1}$	Reduced speed	Wind gusts $\geq 26 \text{ m s}^{-1}$ in 12–48 h	High wind watch: Vehicle instability, damage to power lines and small structures due to falling trees
	$\text{WG} \geq 32 \text{ m s}^{-1}$	Road closed, high number of fallen trees	$> 25 \text{ m s}^{-1}$	Road closed	Wind gusts $\geq 26 \text{ m s}^{-1}$ in 36 h	High wind warning: Vehicle instability and loss of control, difficult driving conditions

Note: For the United States, the values were converted from the US unit to International unit (na means not available).

Table 2 Three different approaches to model natural hazards and their consequences, with arguments for (pro) and against (cons)

<i>Model</i>	<i>Description</i>	<i>Pros</i>	<i>Cons</i>
Analytical	Identification of risk/failure states through logical structures (e.g., risk matrix)	Easy to apply	Not suitable for large-scale investigation
Simulation	Representation of potential post-disaster consequences given a range of starting conditions	Random large sample of scenarios	Offer separated decision strategies, sub-optimal for decision-making to due uncertainty
Optimization	Determination of the optimal network according to the maximization of a range of parameters	Capable of providing decisions to address multiple possible future damage events	Input-data demanding, high-level of sophistication

Modeling Methods

Since adverse weather events are unpredictable in their frequency, location, and intensity, risk-based modeling techniques have been developed in order to plan for likely consequences. Each community/sector faces differing threats and need strategies fitted to their context. For example, models can support carriers to anticipate and plan for supply chain resilience in the face of broad disruptions. Also, models are suitable for investigating the need of relocating highly vulnerable structures (e.g., bridges). Models are particularly useful for testing adaptation options (i.e., strategic interventions) to understand if investments for improving resilience will save money in the long term.

Different approaches exist to model natural hazards and their consequences (Table 2). These models can be categorized as: (1) analytical, (2) simulation, or (3) optimization models (Faturechi and Miller-Hooks, 2014). Depending on data availability, they can be applied to different hazards.

Analytical methods investigate potential failure and risk states using disaster probabilities and consequences through different forms of logical structures, for example, risk matrix. Simulation methods are scenarios-based methods in which a range of potential situations is generated to evaluate the degradation of the network (by comparing pre-and post-performance level of service). Monte Carlo simulation considers random damage states and probability of occurrence to generate a large sample of scenarios. Optimization models optimize one or more network performance function (e.g., traffic flow), whether they are deterministic (ignoring events probability) or stochastic (considering events probability). They are mostly employed for pre-disaster planning and post-disaster resource allocation. They are suitable to capture the non-recurrent and uncertain nature of disaster impacts, supporting decisions to address multiple possible future damage events.

A model can be obtained by combining different heterogeneous models; in this case, the single models are organized in modules with distinctive processes and input data. For exchanging data and working together, input and output data must be compatible between the models. User-friendly interfaces can be created in order to facilitate the adoption of the final model. All models should be validated in order to be a good representation of reality; however, this is usually a challenging task due to data availability and rarity of extreme events. Data from sensors or large database are a promising resource for this purpose.

International Case Studies

Three case studies are presented to illustrate the application of simulation models to assess adverse-weather impact to roads. Each study shows a combination of models to integrate hazard, exposure, and vulnerability aiming at identifying road links at risk and impact at network-level.

Flash Flood Impact to Roads in Europe (Newcastle, United Kingdom)

This case study shows the impact of heavy rainfall in terms of flood to the urban road network by means of a simulation model of a middle-size city in the United Kingdom, Newcastle-upon-Tyne (Pregolato et al., 2016).

In this study, a risk-based framework for assessing the disruption to the urban road network from flood events was presented. This framework coupled a flood and a transport model to assess the impacts of extreme rainfall events, and to quantify the resilience value of different adaptation options. This study showed that extreme flooding events can cause the increase of travel times by up to 50%, while adaptation options can reduce transport disruption from flooding by reducing delays in travel times up to 22% (Fig. 2).

The proposed method can be used to optimize investment and target limited resources at critical locations, providing means of prioritizing limited financial resources to improve resilience. This is particularly important, as flood management investments must typically exceed a far higher benefit-cost threshold than transport infrastructure investments. By capturing the value to the transport network from flood management interventions, it is possible to create new business models that provide benefits to, and enhance the resilience of, both transport and flood risk management infrastructures.

Flood Impact to Roads in Japan (Nagoya)

This case study shows the impact of torrential rain (typhoon) and the consequent flash flood on the urban road network in Nagoya, Japan (Wisetjindawat et al., 2018). The study uses a stochastic modeling approach that assigns a failure probability to each road segment based on climate-model outputs for the region, which is later used to determine the travel time reliability between any given

Figure 2 The impact of flooding on the road network of Newcastle upon Tyne (UK) (Pregnotato et al., 2016). (a) the flood hazard map for the city council area; (b) the road network; (c) the flood-transport curve that relates flood depth and vehicle speed during flooding; (d) flooding impact on the network as a result.

origin-destination pair. Travel time reliability represents the probability that a trip between a given origin-destination pair can be completed within a given time duration. For example, the simulation result estimates that there is a 70% probability that a trip between Nagoya city center and Tajimi can be made within a travel time 4-times higher than usual during the typhoon (Fig. 3).

The method can be used to evaluate the effectiveness of multiple policy schemes to reduce the impacts of an extreme weather event. For example, the model was used to evaluate two types of policy measures: (1) infrastructure management schemes (e.g., strengthening heavily used roads, thus reducing the failure probability of major roads) and (2) demand management schemes (e.g., changing departure time or adopting work-from-home schemes). Although it was found that strengthening important roads had a bigger impact in relieving congestion than delaying departure time, combining both strategies can better alleviate the congestion.

Flash Flood Impact to Roads in the United States (Various Cities)

This case study shows the impact of flash flood events on an urban road network considering changes in precipitation patterns under two different climate scenarios (high and low climate change scenarios) by simulating flash floods in five different cities in United States, namely: Boston (Massachusetts), Houston (Texas), Miami (Florida), Oklahoma City (Oklahoma), and Philadelphia (Pennsylvania) (Kermanshah et al., 2017). In this study, a vulnerability assessment framework for urban road networks against extreme rainfall-induced flash floods was presented. The framework coupled climate models, network modeling, GIS, and stochastic modeling to compile a "vulnerability surface" for each city in each climate scenario. More specifically, the impact of simulated extreme flash floods was assessed using percentage drops in static (i.e., overall properties and robustness topological indicators) and dynamic (i.e., accessibility and travel demand metrics) network properties and combined these metrics for each climate scenario onto one vulnerability surface. A vulnerability surface is the polygon created by a spider diagram that each axis is the percentage drop in one metric.

This study showed that flash floods and climate change are bound to seriously impact cities across the United States (Fig. 4). Generally, flash floods can have a significant impact on road networks and the magnitude of these impacts are mainly related to the geographic location of the cities, size of the road networks, and also the projection of climate scenarios. Moreover, different metrics can capture different resilience aspects of a road network. For example, in Houston resulted the most vulnerable city to flash floods in

Figure 3 The impact of the simulated typhoon on roads and travel condition in Tokai Region (Nagoya, Japan) (Wisetjindawat et al., 2018). (a) map of 24-hr-typhoon rainfall; (b) observed degraded road network; (c) predicted road failure probability; (d) travel time reliability from Central Nagoya city to Tajimi city at different departure times; (e) average travel speed during the typhoon at 18:00.

high climate change scenario where on average the 8% of road networks were impacted causing more than 30% loss in long-distance accessibility in the city.

The proposed approach can be reproduced in different cities around the world, and researchers can use the results as guidelines for infrastructure design and planning purposes. From a policy perspective, governments can prioritize adaptation policies (e.g., infrastructure maintenance) in regions with a higher risk of vulnerability and allocate more resources to them. This can also reduce possible economic losses in those regions in future. Also, they can alter their urban infrastructure design criteria to adapt to climate change. For example, by changing the design criteria (by simulating green infrastructures such as street planters and permeable pavement) stormwater management strategies can be tested to reduce the catastrophic impacts of extreme flash floods.

Discussion and Research Challenges

The resilience of transport systems is highly dependent on geography. In the previous sections, we have learned how different countries assess impacts through thresholds and scenarios simulation. Each country develops its own standard, which is adapted to suit its specific geography and needs. Some countries, such as Japan, are prone to large-scale disasters, thus tend to focus more on evacuation plans. In the United Kingdom, floods happen more regularly but will less catastrophic aftermath; therefore, the focus is more on alleviating travel interruptions and severe traffic congestions. In the United States, because of the size of the country, each state has special weather condition and therefore, the weather hazards are totally different in each state and some regions experience natural hazards like hurricanes that will never happen in other countries.

In terms of modeling approaches, in addition to functional measures, topological measures from graph theory (e.g., connectivity and betweenness centrality) can be adopted to consider the network as a system of links and nodes. This method gives an insight into the weaknesses and is able to identify the important and vulnerable locations. In the third case study (United States), the authors adopted a graph theory approach to identify vulnerable locations in the system. More specifically, they calculated the changes in betweenness centralities (which can be a representative of the traffic volume), alongside with five other metrics like accessibilities, after the simulated flash floods to find out the vulnerable regions of the road networks.

Validation is a tricky stage of modeling, since data are not always available in the needed type, quality, or format. We recommend standardizing the data and collect it for a larger set of disasters, preferably in a GIS format to enable onward use.

Figure 4 The impact of flash floods on the road networks in United States (Kermanshah et al., 2017). The left panel explains the framework used for the vulnerability assessment of road networks using (a) stochastic methodology for different climate scenarios; (b) the vulnerability surface method that combines different metrics in one single number. The right panel presents a case study on road network of Houston, Texas: (c) extracting precipitation data from climate models; (d) climate failure rate for the area; (e) resulting vulnerability surface.

Despite efforts in increasing infrastructure resilience, achieving a complete no-fail infrastructure is an impossible task. Infrastructure management is not isolated and limited to the physical assets, but imbedded in the complexity of the built environment and strongly linked to the users' demand and behavior. For example, most commuters tend to underestimate the risk of travel during adverse weather and continue their usual travel habits. Hence, along with improving the infrastructure, establishing an efficient communication and education on the risk of travel at different level of hazards with commuters is important.

Although this chapter focuses on the road system, transport sector widely embraces all the other means (such as rail, aviation, and navigation). Deep analysis should incorporate complexities of the real world, including the interdependencies underlying urban environment focusing on cascading effects and interconnected failures. For the same reason, studies are moving from a "single-hazard" to a "multi-hazard" approach, looking at the effects of compounding events (e.g., flooding that triggers landslides).

In the near future, autonomous vehicles are expected to share the transport infrastructure with other conventional vehicles and pedestrians; these vehicles are highly dependent on sensors and wireless communication between vehicles-to-vehicles and vehicles-to-infrastructures. Further studies should address how adverse weather might increase failures in vehicles' perception of obstacles or induce the likelihood of errors in the communication to design a robust system less vulnerable to environmental (cascading) impacts.

Conclusion

Up-to-date well-functioning transportation systems are fundamental for modern societies, who rely on infrastructure for everyday activities. Transportation systems are vulnerable to adverse weather events and the impact of such phenomena in cities can potentially cripple the flow of life for millions of people. Considering the magnitude of societal debilitation that these events can cause to cities, increasing efficiency and resiliency in urban transportation system is pivotal to protect our cities and surrounding areas.

This chapter provided an overview about transport resilience, illustrating the impact of adverse weather events to roads. Analytical, simulation, and optimization models were explained, as tools to study transport resilience problems. Three international case studies were presented as examples of application of simulation models looking at the impact of flooding on road networks in

different areas of the world. Such case studies could be extended by considering the interdependence with another infrastructure type, or the effect of technology change (e.g., autonomous vehicles) or multiple hazards.

In addition to flooding, winter storms can have a crippling effect on any transportation systems. Air and sea traffic, as well as railways and highways, especially in remote rural areas, can be closed down for hours or even days during times of heavy snowfall or ice events. The Chapter 10176: *Roadway Pavement Conditions and Various Summer and Winter Maintenance Strategies* discusses the safety effect of different winter-maintenance strategies for highways.

Introduction

Wrong-way driving (WWD) is the act of driving against the legal direction of traffic flow. This article covers only WWD on high-speed limited access facilities (e.g., freeways, expressways, and multilane divided highways), and that is what WWD stands for in the text. Although this type of event is rare, it is a serious traffic safety issue due to the severe outcomes of the crashes resulting from WWD. Typically, WWD crashes are head-on or opposite-direction sideswipe collisions at high speeds, which result in multiple fatalities and/or severe injuries. However, WWD crashes occur at low speed too, typically at cloverleaf ramps where only a yellow stripe separates traffic in the two directions. These crashes occur on what is part of the limited-access facility but of a different character—more similar to head-on collisions on rural two-lane highways—than what is the focus of this article. According to the WWD crash data, an average of 265 such fatal crashes resulting in 355 deaths occurred annually in the United States from 2004 to 2013 (Baratian-Ghorghi et al., 2014a). In terms of magnitude, WWD fatal crashes and fatalities are comparable to those occurring at highway-rail grade crossings (HRGX). However, unlike the HRGX experience, WWD has not been declining over the years. Fig. 1 compares the overall trends of all traffic fatalities to those that are specifically WWD-related in the United States over the 10-year study period. This figure illustrates that overall traffic fatalities declined substantially from 2004 to 2013, while WWD fatalities remained almost unchanged. A comprehensive national analysis has not been done for the years after 2013, but preliminary data indicate that the situation has not improved. There has been little sustained, coordinated national campaign to address WWD, which may somewhat explain this difference. It also suggests that such an effort could make a positive difference by helping to align WWD with overall national traffic safety trends. In other countries, WWD is also a serious issue of similar magnitude, and, in some countries, intentional WWD—the so-called ghost driving—seems to be more common than in the United States.

Fig. 2 depicts the annual average frequency of WWD fatalities across all 50 US states. In these illustrations, Group 1 includes 16 states with more than 2% of WWD fatalities, Group 2 represents states with less than 2% but more than 1%, and Group 3 consists of the states with less than 1% WWD fatalities (Zhou and Pour-Rouholamin, 2014a). Texas is ranked first with more than 15% of WWD fatalities occurring, followed by California and Florida. The three states with the highest frequency comprise approximately one-third of total WWD fatalities in the United States. Furthermore, these three states have put a considerable amount of efforts and investment in solving the WWD issue, given the significance of this problem in their jurisdictions.

Much of the focus of WWD research has been dedicated to their occurrences on freeways since this type of roadway has the highest speed and thus the outcomes of WWD crashes are most severe. As such, the discussion in the remaining part of this article primarily focuses on WWD crashes on freeways. Specifically, the discussion covers the following areas: (1) contributing factors to WWD crashes; (2) current traditional and advanced safety countermeasures to mitigate WWD crashes; and (3) future systemic safety approach to combat WWD.

Contributing Factors

The special investigation report of National Transportation Safety Board (NTSB) reported that impaired drivers constitute an alarming 60% of fatal WWD crashes (NTSB, 2012). This number might be even higher as some WWD drivers either refused to take sobriety test or had no test results recorded in the crash reports. NTSB also reported that the drivers who are older than 70 years have greater odds of being involved in WWD crashes than non-WWD crashes. Other studies found that most WWD events occur during the early morning hours (12–5 a.m.) of weekend days; this is possibly related to high alcohol consumptions at those times. In addition, poor lighting condition and severe weather may contribute to the occurrences of WWD crashes. The findings of the studies

Figure 1 Overall fatalities versus WWD fatalities in the United States (2004–13).

conducted in California, Texas, Florida, North Carolina, Illinois, Alabama, Arizona, and other states are consistent to NTSB special investigation report (Zhou et al., 2015a, 2017a, 2017b; Ponnaluri, 2016; Lathrop et al., 2010; Braam, 2006). Most of the past studies on contributing factors to WWD crashes were based on the crash reports that provide little information on roadway conditions. Therefore, the results might be biased and focused more on the drivers' errors. There are a number of other factors that may increase the probability of WWD occurrence on a roadway facility. For instance, studies also found that inconsistency in location, angle, and size of wrong-way-related traffic signs, lack of pavement markings, and improper geometric design plays a significant role (Zhou and Pour-Rouholamin, 2014a). Typically, wrong-way drivers enter controlled access highways through their exit ramps. Particularly, the partial cloverleaf ramp terminals with parallel two-way ramps increase driver confusions and contribute to a major portion of the WWD events (Morena and Leix, 2012; Cooner et al., 2004). Although WWD movements sometimes originate from making U-turns on the mainline or at median crossover, they account for only a small portion of all WWD events. A study in Illinois showed that only 6.5% of 217 confirmed WWD crashes occurred from wrong-way drivers making U-turns on the mainline, while the other 93.5% likely occurred from drivers entering the freeway through exit ramps (Zhou and Pour-Rouholamin, 2015; Zhou et al., 2012). Therefore, the geometric design characteristics and usage of traffic control devices (TCDs) at the exit ramp terminals as well as along the ramps are critical in reducing the occurrence of WWD crashes on freeways. Although properly designed geometric features can physically obstruct the drivers from entering wrong way, proper use of wrong-way-related TCDs can help the drivers to take corrective measures if they mistakenly enter wrong way.

Safety Countermeasures

Over the last few decades, different engineering countermeasures have been proposed, implemented, and tested by various state and local transportation agencies to mitigate WWD activities, including (1) changing the size, location, and angle of wrong-way-related traffic signs, (2) proper use of conventional and innovative pavement markings, (3) implementing proper geometric elements (raised medians, channelizing islands, and control radii at intersections), and (4) application of intelligent transportation systems (ITS). The following sections briefly discuss these countermeasures and their potential application in combating WWD crashes.

Signs, Pavement Markings, and Traffic Signals

Signs are among the more traditional and least expensive WWD countermeasures. They are meant to guide, warn, or regulate drivers, and, in the WWD context, deter them from making wrong-way maneuvers at the intersections of exit ramps and crossroads. Proper signage can notify the wrong-way driver that she/he is traveling in the wrong direction should it occur. Commonly used wrong-way-related signs used in the United States include DO NOT ENTER, WRONG WAY, ONE WAY, keep right, and turn prohibition signs. The effectiveness of these signs greatly depends on the location, orientation, size, and nighttime visibility. The following general considerations are recommended to increase the effectiveness of WW-related signs:

- Ensure that signs are positioned to face, and are clearly visible to the driver for whom signs are placed.
- Place the first set of WRONG WAY signs within 200 feet from the exit ramp terminal, so that these signs are clearly visible to the drivers on the crossroad when they are approaching the exit ramp terminals.
- Consider optional use of oversized sign and/or supplemental signs to enhance their visibility and conspicuity.
- Evaluate the use of lower mounting height of DO NOT ENTER and WRONG WAY signs where appropriate.
- Consider various optional enhancements to increase conspicuity of signs (particularly at night), including red retroreflective strips on sign supports, flashing LED borders, or flashing beacon.

Figure 2 Percentage of WWD fatalities in each state (2004-13).

Pavement markings, like other TCDs, are a way of communicating with drivers and they can convey important messages about proper and safe road use. Types of pavement markings used to address WWD include longitudinal lines, lane line extensions, lane-use arrows, wrong-way arrows, and delineation. Detailed information about designing these arrows and their dimensions can be found in *Standard Highway Signs and Markings* by Federal Highway Administration (FHWA, 2004). Some key considerations for effective use of pavement markings to reduce WWD are as follows:

- Ensure that pavement markings complement the geometry of the location and provide positive guidance to drivers about proper direction and movement.
- Ensure that pavement markings and signs are consistent with one another so they reinforce the information conveyed to drivers.
- Consider various optional enhancements to increase conspicuity of pavement markings.

Most exit ramp terminals, if signalized, currently use circular green signals supplemented with No Right/Left Turn signs. Some locations use green arrow signals. Field observations show that green arrow signals send a more obvious message to drivers and can

Figure 3 Analogous traffic signals for exclusive through lanes.

replace a circular green signal with a No Right/Left Turn sign. As shown in [Fig. 3](#), the combination of a circular *green* indication and a turn prohibition sign (No Right Turn shown in the figure) mounted on the mast arm traffic signal for an exclusive through-lane has the same meaning as a *green* arrow indication (through only).

The placement of WW-related signs/markings can vary considerably depending on the interchange types. For instance, the appropriate placements are different between diamond and partial cloverleaf interchange due to their difference in geometric configurations at the exit ramp terminals. Therefore, signs and pavement markings should be placed where it complements the geometry of interchange and provide positive guidance about proper direction and movement. A detailed guideline for appropriate application of WW-related signs and markings at different types of interchanges can be found in *Guidelines for Reducing Wrong-Way Driving Crashes on Freeways* by the Illinois Department of Transportation (IDOT) ([Zhou and Pour-Rouholamin, 2014a](#)) and *Manual on Uniform Traffic Control Devices (MUTCD) 2009* by FHWA (2009). A historical evolution on wrong-way-related TCDs in MUTCD was summarized by [Baratian-Ghorghi and Zhou \(2017\)](#).

Geometric Design Features

Past studies have indicated that certain interchange configurations and geometric design elements may be more susceptible to WWD and that minor geometric changes to ramps can reduce wrong-way movements onto freeways. In this section, geometric elements that are capable of discouraging wrong-way maneuvers are identified. Those elements should be given special considerations during the design stage of interchanges and ramp intersections.

Exit ramp terminals are highly critical points because they can be the entry locations from which wrong-way maneuvers originate. Their geometric characteristics (arrangement, angle with crossroad, cross-section, etc.) are of high importance. For instance, adjacent exit and entrance ramps (parallel, side by side) may be more prone to wrong-way maneuvers when there is a nearby side street. Therefore, care should be taken to consider how each geometric characteristic can make a location more susceptible or less susceptible to WWD. In general, use of acute angles to connect the exit ramps to one-way crossroads and obtuse angles to connect with two-way crossroads is recommended to better convey direction of travel. Use of sweeping connections to crossroads is reported to be less susceptible to WWD because they form acute angles with crossroads where turning movements in either direction are not allowed. Reducing the width of exit ramp throats by placing channelizing islands and increasing the width of entrance ramp throats by removing islands can be helpful in reducing WWD. Non-traversable raised median on the crossroad may help reducing left-turning wrong-way drivers from the crossroads. On the other hand, to reduce wrong-way right turns (particularly at diamond interchanges), a short-radius curve or angular break at the intersection of the left-edge of exit ramps and the right edge of crossroads is recommended. An open sight distance should be provided for drivers from crossroads to see the entire length of ramps. To ensure the visibility at night, uniform lighting levels should be provided for both entrance and exit ramps. At the intersection of two-way ramps and crossroads (partial cloverleaf interchanges), the stop lines for left turns from crossroads should be moved forward so the motorists have a better view of the entrance ramp and a shorter left-turning radius.

There are certain geometric features that are more susceptible to WWD, which should be avoided when possible to reduce the chance of WWD. Some of the examples may include: adjacent entrance and exit ramps intersecting a crossroad ([Fig. 4](#)), isolated exit ramps, left-side exit ramps ([Fig. 5](#)), one-way exit ramps connected as unchannelized T-intersections, exit ramps intersecting with two-way frontage roads, less common arrangement of exit ramps (e.g., buttonhook or J-shaped ramp, as shown in [Fig. 6](#), connected to a parallel or diagonal street of frontage road), temporary ramp terminals at work zones, freeway feeders (where exit ramps transition into local roads), side streets adjacent to exit ramps ([Fig. 7](#)), and scissors channelization ([Fig. 8](#)).

Intelligent Transportation Systems (ITS)

ITS technologies have been recently used by many transportation agencies to develop WWD countermeasures. The application of ITS in detecting and deterring WWD incidents consists of three steps: (1) detection, (2) warning, and (3) action. Detection step can be accomplished using a variety of different detectors such as inductive loop detectors (ILD), video image processing (VIP) systems, microwave radar-based traffic detection systems, infrared detection systems, and others. Regarding the warning step, we note that different methods can be employed to warn both wrong-way and right-way drivers. In-pavement warning lights, flashing wrong-way signs, warning lights, and dynamic message signs (DMS) are some examples of these warning systems. Action can be taken by patrol

Figure 7 Side streets adjacent to exit ramps.

Figure 8 Scissors channelization with possible movements.

units or other responsible parties after receiving an alert from the traffic management center (TMC) or some centralized dispatches to intercept wrong-way drivers. A typical scheme of ITS detection and warning system for WWD can be found in [Fig. 9](#).

As shown in [Fig. 9](#), a WW driver is first detected using sensor technologies, and she/he is immediately notified of the mistake by means of warning devices such as LED WW signs. These work well in rural areas where modern TMCs and quick responses by police are not available. In some large metropolitan areas, TMCs can receive the signals from field detectors and sensors and further verify WWD using video cameras. After the incident is verified, law enforcement officers will be provided with the location and direction of the wrong-way driver through dispatch centers. Law enforcement officers and other incident responders can either help at-fault vehicles correct their directions or stop them. Meanwhile, pertinent messages can be posted on changeable message signs (CMSs) to notify right-way drivers of the presence of errant drivers.

Given that the vast majority of WWD crashes are caused by driving under the influence (DUI) of alcohol or drugs, the traditional WWD countermeasures might not be capable to reduce the crashes by drunk drivers. Therefore, WWD detection and warning systems may be more required. According to the past studies, only a small portion of transportation agencies exploited ITS technologies to identify WW drivers and to take prompt and proactive actions. Radar detectors, closed-circuit television (CCTV) cameras, and ILDs were used as popular detectors. After detection, flashing WW signs, warning signs, and DMS are available means of warning other drivers of an imminent danger ahead. Various messages may appear on DMS such as "Wrong-Way Driver Ahead" and "All Traffic Move to Shoulder and Stop." After detection and verification of the at-fault driver, patrol units may step in and position ahead of the WW driver to either help the driver pull over or to correct his or her direction. If it is not possible to position, responding units may attempt to intercept the vehicle by deploying tire deflation devices (e.g., portable spike) to slow or stop the WW driver or by using extra force to stop the vehicle.

In the United States, there are several existing systems that apply ITS technologies for WWD detection and warning. The Harris County Toll Road Authority ([HCTRA, 2012](#)) in Houston, Texas, implemented a radar-based WWD detection system. This system was

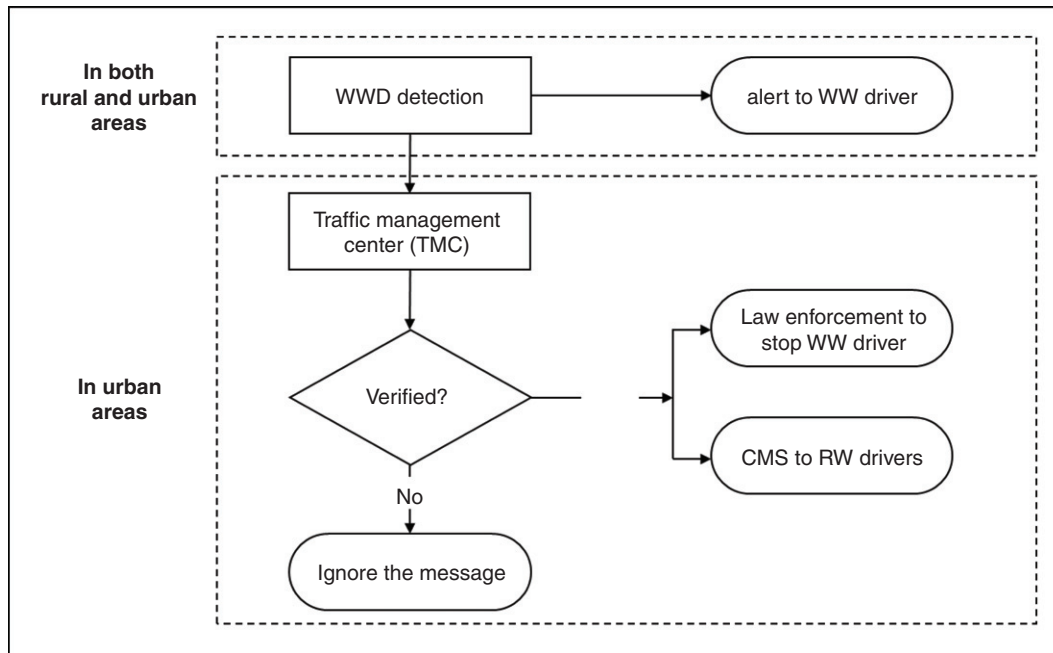

Figure 9 Typical scheme of WWD detection and warning system.

designed for 12 sites at exit ramps and along the mainline, all connected to the HCTRA TMC, at an overall cost of \$337,000. The New York State Thruway Authority (Thruway) implemented an ITS-based, wrong-way entry warning system at Porter Avenue (Exit 9) along I-190 in Buffalo, New York. The system consists of two major components: Doppler radar detection and programmable CMSs. Arizona Department of Transportation (ADOT) recently implemented a thermal-detection technology, the first-of-its-kind camera detection system, to mitigate WWD crashes (AZCentral, 2018). This system consists of 90 thermal-detection cameras placed on exit ramps and the mainline of I-17 in Phoenix, Arizona, at an overall cost of \$4 million. It takes a three-phase approach in case a WW vehicle is detected including alerting WW drivers thus they can self-correct themselves, warning right-way drivers, and informing law enforcement.

In addition to the traditional ITS application, several studies explored the application of connected and autonomous vehicle technologies, which uses vehicle-to-infrastructure (V2I) and vehicle-to-vehicle (V2V) communication, for developing wrong-way driver detection and warning system. In 2016, the Texas A&M Transportation Institute (TTI) developed an initial concept for a connected vehicle WWD detection and management system, which would detect WWD vehicles, notify the Texas Department of Transportation (TxDOT) and law enforcement personnel, and alert affected travelers (Finley et al., 2016). In 2007, a driver assistance program was developed in Germany, which uses the in-vehicle navigation system to automatically recognize when a driver enters the wrong direction in a roadway and provides a series of audible and visual warnings in the heads-up display (HUD) (Brigl, 2007). Using V2V communication, the program was also capable of warning other motorists within 2000 feet of the wrong-way driver. The V2I technology was used for communicating information to vehicles in a wider area, in which the wrong-way vehicle sends its position to a service center, and the service center disseminates this information to other vehicles.

Although not common in the United States, WWD originated from ghost driving has been critical safety issue in some European countries including Germany and France. By definition, ghost driving is the act of driving in the wrong direction to travel from one interchange to another interchange. Several detection and alert systems have been introduced to reduce crashes resulting from this type of WWD events. In France, when a ghost driver alert is sent out, roadway operators attempt to confine the problem promptly by activating electronic signs at roadway entry points and closing access to the road using physical barriers. In Germany, an electronic system is being experimented that will reactively warn drivers through visual and acoustic means of imminent threat. For further details on this topic, interested readers are referred to *Preventing and Managing Ghost-Driver Incidents: The French Experience* (Vicedo, 2007) and *Ghost Drivers: A Direct Experience of Toll Road Operators* (ASECAP, 2017).

Systemic Safety Approach for Reducing WWD Crashes

Previous literature shows some evidence that the WWD risks can be attributed to some common risk factors, which indicate that a proactive systemic safety approach can be developed to address the WWD issue on freeways. A systemic approach involves making improvements at locations with high-risk roadway features or high-predicted crash risk correlated with particular severe crash types, regardless of the actual crash history. It is a more proactive approach than a spot safety or a corridor retrofit approach that focuses

Figure 10 Systemic safety approach for reducing WWD crashes.

only on treating specific locations with a crash history and less costly than systematic approach that makes improvements at all sites in an area, regardless of predicted crash risk or crash history. Since WWD crashes are rare events, it is challenging to select hot spots for WWD countermeasures based on crash history alone. In addition, the selection of locations for WWD countermeasures based on engineering judgments alone may not be sufficient in most cases since the occurrences of WWD events are often resulted from the combined effect of a wide range of contributing factors. The complex relationship among all these contributing factors cannot be accounted by engineering judgments alone. Therefore, a systemic approach could be an ideal tool for transportation agencies to mitigate WWD activities within their jurisdiction by acting proactively and ensuring an efficient use of their limited funding.

A systemic approach to address the WWD issue on limited access motorways would involve the seven steps shown in [Fig. 10](#). Step 1 involves defining the project scope. Depending on the interest of a particular transportation entity, the project scope can be the exit ramp terminals along a specific segment of a freeway or all the exit ramp terminals along the freeways within their jurisdiction. After defining the scope of the project, steps 2–4 help to identify and verify the locations (i.e., the exit ramp terminals) having highest risk of WWD. Steps 5–7 involve selecting potential countermeasures to reduce WWD risk at those locations, implementing countermeasures, and evaluating their impacts on reducing the risk of WWD. The most challenging part of developing a systemic safety approach for WWD crashes is the identification of locations with high-predicted crash risk. As mentioned earlier, WWD crashes are rare events on our roadways, which make it difficult to develop predictive crash-risk models for these kinds of crashes. However, in recent years, a number of researchers made significant efforts to develop WWD crash-risk prediction models. The works of [Atiquzzaman \(2019\)](#), [Atiquzzaman and Zhou \(2018a\)](#), [Sandt et al. \(2017\)](#), [Rogers et al. \(2016\)](#), [Pour-Rouholamin \(2016\)](#), and [Baratian-Ghorghi et al. \(2014b\)](#) are some examples of efforts to develop WWD crash-risk prediction models. These studies explored the idea of predicting WWD risk at an individual exit ramp terminals or along a specific roadway segment based on the geometric design, usage of TCDs, traffic characteristics, WWD incidents (i.e., citations and/or 911 calls), etc. Transportation agencies can take advantage of the probabilistic/linear models developed in these studies to identify high-risk locations, which will enable them to adopt a systemic approach to reduce WWD crashes within their jurisdictions.

Discussions

Historically, it has been difficult to study the characteristics of WWD crashes due to the rareness of these types of crashes. Additionally, it is difficult to identify the true WWD crashes from a crash database alone. The identification of true WWD crashes may involve reviewing the crash narratives in the crash reports, which is time-consuming and laborious. Having said that, looking at the crash data alone may not be sufficient to perceive the actual gravity of WWD problems on motorways. Looking at the WWD incidents along with crash data is probably the best way to understand the underlying characteristics of wrong-way drivers on a certain location/facility. Based on their occurrences, WWD incidents can be categorized into three broad groups—recurring, intentional, and random incidents.

Recurring incidents happens regularly mainly due to the geometric design deficiencies. For instance, an average of 17 WWD incidents during a typical weekend was reported at the I-65 Exit 284 southbound ramp terminal in Alabama, United States. The potential design deficiencies that might have contributed to the recurring WWD movements at this location include a traversable median on crossroad, narrow median width between exit and entrance ramp, faded pavement markings, lack of proper signage, and

inadequate sight distance for drivers turning left from crossroad to the entrance ramp. Intentional WWD incidents are caused by a combination of roadway design deficiency and undesirable driving behaviors. For instance, there were 15 WWD movements over a 48-hours video monitoring at an intersection on a rural divided highway near a gas station in Alabama, United States. WWD movements at this location were due to the fact that the drivers exiting from the gas station were inclined to drive wrong way to make a shortcut instead of driving downstream until the next median opening to make a U-turn. A combination of access control and education strategies is needed to reduce this type of incident. However, intentional WWD incidents also include suicidal attempts and ghost driving, which may only be addressed through public awareness, stricter enforcement, and application of ITS. Random WWD incidents are primarily caused by impaired driving. WWD with a suicidal attempt also falls into this category. ITS technologies and quick incident responses can work together to reduce this type of incident and prevent related WWD crashes.

Prevention of recurring WWD incidents greatly depends on the geometric design and TCDs at the exit ramp terminals, where most WWD drivers enter wrong way initially. Therefore, careful considerations should be taken at the design stage of an exit ramp terminal to make it less susceptible to WWD. Signs and pavement markings should be oriented and placed carefully to complement the geometric design so that it is a positive source of information to the motorists and helps them make corrective measures quickly when someone enters wrong way or to prevent them from going wrong way in the first place.

Given the current rapid technological advancement, the available ITS technologies are becoming less costly, which indicates that many transportation agencies will adopt ITS technologies to mitigate WWD crashes within their jurisdiction. In addition, if the connected and autonomous vehicles become open to public use, it is likely that these vehicles will be equipped with special safety features that warn the motorists should it go wrong way and also disseminate information to the nearby right-way drivers to inform them about the imminent wrong-way driver.

Over the years, in the context of WWD, many transportation agencies have struggled to select locations for safety improvements because these crashes are rare and thus difficult to find hot spots based on the historical crash data. To overcome this issue, the transportation agencies may consider adopting a systemic safety approach, taking advantage of the available WWD crash-risk prediction models, to address WWD proactively.

Having said that, engineering countermeasures alone may not be enough to combat WWD crashes by impaired driving or intentional WWD activities. For instance, a study conducted by TTI reported that lowering the height of the white-on-red signs, making the signs larger (i.e., oversized), adding a red retroreflective sheeting on the sign support, or adding red flashing LEDs around the border of the sign did not improve the ability of alcohol impaired drivers to locate WRONG WAY signs. Therefore, to combat the WWD resulting from impaired drivers or undesirable driving behaviors, the best options for the transportation agencies are education and enforcement, possibly combined with making it impossible to drive a vehicle with alcohol on one's breath, but that is a topic for a different article. Transportation agencies are recommended to organize regular educational campaigns and media coverages, and adopt stricter enforcements to combat WWD resulting from impaired driving within their jurisdictions.

INTRODUCTION

Roger Vickerman

In an increasingly globalized world, despite reductions in costs and time, transportation has become even more important as a facilitator of economic and human interaction; this is reflected in technical advances in transportation systems, increasing interest in how transportation interacts with society and the need to provide novel approaches to understand its impacts. This has become particularly acute with the impact that Covid-19 has had on transportation across the world, at local, national, and international levels. This Encyclopedia brings a cross-cutting and integrated approach to all aspects of transportation from work in many disciplinary fields, engineering, operations research, economics, geography, and sociology to understand the changes taking place.

Transportation is both influenced by, and an influencer of, changes in the economy and society. Increasing speeds have reduced journey times and made the world a smaller place as globalization has affected both where people live and work and from where they source their goods and materials. Increasing volumes of traffic, often on old and life-expired infrastructure, lead to congestion and delays. Constraints on public budgets have led to increasing pressure on the private sector to fund improvements requiring new and innovative financial solutions. While there are clear differences in the nature of the pressures felt in the developed and less developed economies, there is an increasing recognition that in all societies, there is an accessibility problem such that certain groups become disadvantaged by the lack of access to reliable and cost-effective transport. While the problems are clearly multidimensional, research on transportation is often constrained by single disciplinary approaches and this carries over into the practice of transport planning and policy. The Encyclopedia cuts across these artificial boundaries by taking an approach that emphasizes the interaction between the different aspects of research and aims to offer new solutions to understand these problems. Each of the nine sections is based around a familiar dimension of work on transportation, but brings together the views of experts from different disciplinary perspectives. Each section is edited by an expert in the relevant field who has sought chapters from a range of authors representing different disciplines, different parts of the world, and different social perspectives. In this way, the work is not just a reflection of the state of the art that serves as a starting point for researchers and practitioners, but also a pointer toward new approaches, new ways of thinking, and novel solutions to problems.

The nine sections are structured around the following themes: Transport Modes; Freight Transport and Logistics; Transport Safety and Security; Transport Economics; Traffic Management; Transport Modeling and Data Management; Transport Policy and Planning; Transport Psychology; Sustainability and Health Issues in Transportation. Some of the chapters provide a technical introduction to a topic while others provide a bridge between topics or a more future-oriented view of new research areas or challenges. While there is guidance to cross-referencing between chapters, readers are encouraged to explore the tables of contents of all the sections to get a full understanding of the issues. Much of the Encyclopedia was completed before the Covid-19 pandemic and clearly this will have changed the situation in many areas covered by this work; the advantage of this type of reference work is that relevant updates will be possible in future editions.

The Encyclopedia has only been possible because of the cooperation of a large number of people. Robert Noland, Georgina Santos, Xiaowen Fu, and Dick Ettema served as an Editorial Advisory Board identifying possible editors of sections and advising on the overall structure. The Section Editors, Edoardo Marcucci, Kevin Cullinane, Per Garder, Maria Börjesson, Edward Chung, Chandra Bhat, Maria Attard, and Carlo Prato,

carried out the work of identifying potential authors of individual chapters, commissioning these, encouraging authors and reviewing drafts. More than 600 authors and co-authors of chapters are, however, ultimately responsible for the success of this venture. Thanks are also due to the key people at Elsevier, particularly the Publishers, Andre Wolff and Oliver Walter, and the Project Managers, Sophie Harrison and Natalie Bentahar; they have shown exemplary patience over more than 3 years in bringing this work to fruition.

LIST OF CONTRIBUTORS TO VOLUME 3

Sharon Cullinane

School of Business, Economics and Law, University of Gothenburg, Gothenburg, Sweden

Kevin Cullinane

School of Business, Economics and Law, University of Gothenburg, Gothenburg, Sweden

David J. Closs

Defining Logistics

So, what is logistics and how is it different from supply chain management? Logistics can be defined as the following:

"Logistics management is that part of supply chain management that plans, implements, and controls the efficient, effective forward and reverse flow and storage of goods, services and related information between the point of origin and the point of consumption in order to meet customers' requirements."
(Council of Supply Chain Management Professionals, 2019).

In contrast, the same organization defines supply chain management as:

"Supply chain management encompasses the planning and management of all activities involved in sourcing and procurement, conversion, and all logistics management activities. Importantly, it also includes coordination and collaboration with channel partners, which can be suppliers, intermediaries, third party service providers, and customers. In essence, supply chain management integrates supply and demand management within and across companies."
(Council of Supply Chain Management Professionals, 2019).

These definitions indicate that logistics management should be considered as a subset of supply chain management. Where the precise boundary between the two is actually drawn, however, is rather fluid. The definition of logistics has become wider over time to include new functions, and it continues to expand today.

Logistics is an integrating and coordinating function, which encompasses the following elements:

- demand forecasting,
- supply forecasting,
- inventory management,
- communications,
- warehousing and storage,
- transportation,
- customer service,
- reverse logistics,
- materials handling,
- order processing,
- procurement,
- order fulfillment,
- logistics network design,
- packaging and assembly, and
- staffing.

Logistics is about delivering the "7 Rights": The Right product in the Right place at the Right time in the Right quantity to the Right customer in the Right condition at the Right cost (Christopher, 2016). A successful logistics function within any organization will integrate seamlessly with other company functions such as marketing, production, finance, IT, and human resource management. In the absence of such seamless integration between the logistics function and other organizational functions, a company's profitability will be undermined so that it is not reaching its full potential. As a consequence of this or any other form of underperformance of the

Figure 1 World merchandise trade volume and real GDP at market exchange rates, 2008–2018 (indices, 2008 = 100). Source: WTO (2019a)

Figure 2 World merchandise trade volume and real GDP growth, 2011–2018 (annual percentage change). Source: WTO (2019a)

logistics function within an organization, when aggregating across all underperforming companies within a nation, it becomes clear that for any country's economy as a whole, GDP will not be maximized (Civelek et al., 2015).

In recent decades, increasing industrialization, the liberalization of national economies and the globalization of production and consumption have all served to fuel greater free trade and a growing demand for consumer products. Thus the trade in physical products (i.e., "merchandise trade") that is facilitated by the logistics industry has grown consistently over time (Fig. 1). In seeking to meet this greatly increased derived demand for its services, the logistics industry has responded by not only expanding to meet the demand, but also by adopting advances in technology that have enhanced efficiency and the quality and range of the services offered. As graphically illustrated in Fig. 1, because of the close historical correlation that exists between the volume of trade and world real GDP, it is actually vitally important that the global logistics industry continues to successfully respond to what appears to be continuous growth in merchandise trade volume.

To emphasize and quantify the precise nature and closeness of the relationship between the volume of merchandise trade and the value of real GDP, Fig. 2 focuses on the growth in both variables over time, as measured in terms of annual percentage change, to reveal how closely they have moved together over recent years.

In order to gain a better insight into the nature of the required response from the logistics industry in facilitating merchandise trade, Fig. 3 shows the most important product groups (in value terms) that are exported around the world, each of which gives rise to different generic forms of logistics solutions. Given the trends in merchandise trade volumes revealed in Figs. 1 and 2, but having a focus on export values rather than volumes, Fig. 3 also implies that export price inflation has not kept pace with the growth in export volumes. Potentially, this may be at least partially attributable to the increasing efficiency of the logistics industry, especially in the light of the economies of scale that are likely to be reaped from the handling of increasing export volumes.

Figure 3 World merchandise exports by product group and annual growth, 2008–2018. ^a US\$ billion and average annual percentage change. Source: WTO (2019a)

In order to complete the macroeconomic picture of the demands that are placed upon the global logistics industry, Fig. 4 gives some insight into the major nations exporting merchandise trade (in value terms) and, by implication, the geographical scope of coverage the international logistics industry is required to respond to.

Freight Transportation

Logistics activities obviously revolve around the movement of freight that potentially can be carried out through the use of several modes of transport. Sometimes, the available modes of freight transport are used individually, on a *unimodal* basis. For example, the

Figure 4 Economies by size of Merchandise Trade, 2018. Note: Includes significant reexports or imports for reexport. Source: WTO (2019b)

movement of a consignment by truck from the factory where it is produced direct to the premises of the end user. On other occasions, however, the available modes of freight transport may be used in combination, on a *multimodal* basis. For example, virtually all international movements of freight by sea or air will require a movement to and from port or airport via another mode, most usually by road but sometimes rail or other modes. The term “intermodal” refers exclusively to a specific subset of multimodal transport where a cargo is moved from origin to destination via two or more modes of transport, but without any transfer between different types of loading unit and, strictly speaking, under a single contract of carriage.

The amount of freight transportation can, of course, be measured in terms of simply the weight of the consignments/shipments/cargoes carried. However, most importantly, this fails to take account of the distance that the freight is carried. Conventionally, therefore, the amount of freight transportation taking place is typically measured in terms of weight and distance combined, most typically in the form of ton-miles or ton-kms. Typically, these are also the basic units used for enumerating the levels of supply and demand for freight transportation.

The main modes of freight transport are sea (using ships of various sizes and types), pipeline, inland waterway, rail, road (mostly using trucks of various shapes and sizes, but also including vans, bicycles etc.), and air (mostly using planes, but may in the future also include an element of drone transport). In addition to these mainstream modes, but often excluded, are cars—since people also carry freight in their cars. Each of these modes of transport has its own characteristics, advantages, and disadvantages, although their precise advantages and disadvantages vary geographically.

By implication, it should be apparent that the geographical scope of freight transport movements range from intercontinental, through international, national (sometimes referred to as domestic), regional, and local. As already suggested, different modes are likely to be used for different geographical levels. Thus, for intercontinental trade (e.g., from China to Europe), the main alternatives will be to move goods by either sea or air, depending on the quantity and the value of the goods being transported. At the other extreme, for local distribution, the main alternatives will be small truck, van, and in urban areas, perhaps moped, bicycle, etc.

In general terms, shipping is used for carrying large consignments of cargo and, almost invariably, represents the cheapest mode of freight transport per unit of weight carried. Because of this and the distances covered by cargoes moved by the shipping mode, it is often said that shipping carries over 90% of world trade, as measured in ton-miles (IMO, 2019) and that “without shipping, half the world would starve and the other half would freeze” (IMO, 2007). Over the past 50 years, estimates of total seaborne trade have grown by approximately a factor of 6, from just over 10 thousand billion ton-miles in 1970 (UNCTAD, 1977) to over 60 thousand billion ton-miles in 2019 (UNCTAD, 2019). The growth in seaborne trade by cargo type over the past 10 years is shown in Fig. 5. What is not really shown, however, is the phenomenal growth in container cargoes which has occurred over the past 50 years; as illustrated in Fig. 5, they now make up a significant proportion of seaborne trade carried, but back in 1970 containerized cargoes formed a mere component of what were classified as “other cargoes,” outside the main cargo types.

In contrast to shipping, freight transport by air is generally used for smaller, more valuable cargoes and, in the majority of cases, is the most expensive mode of freight transport, with the cost of other modes generally falling in-between. Shipping is, however, the slowest mode and air is the fastest and this means that the inventory costs of using shipping are higher than if an airplane is being used.

As mentioned earlier, different countries use different modes. Fig. 6 shows the modes of freight transport used within the European Union.

In most countries, freight transport will consist of a variety of types; movements of goods within the country, exports out of the country, imports into the country, hub movements through a country, and transit movements through a country. For some countries in Europe, such as Belgium, the Netherlands, and Germany, transit movements through the country are very important. In these

Figure 5 International maritime trade in cargo ton-miles, 2000-2019 (estimated billions of ton-miles). ^aIron ore, grain, coal, bauxite/alumina, and phosphate. Source: The figure is own compilation using data published in UNCTAD (2018), which was originally sourced from Clarkson's Research (2018)

Figure 6 Modal split of inland freight transport within the EU, 2017 (% of total ton-kms). Source: The figure is own compilation, based on data from Eurostat (2019a)

cases, the country is merely a bridge between the cargo origin and destination and the vehicle carrying the products may not even stop. Fig. 7 shows the importance of this element of freight transport in the EU.

Logistics Decisions

Thus far, logistics and freight transport have been considered exclusively at a macro level. At a more microlevel, every organization will need to decide on what mode (or combination of modes) of transport it uses, but will also need to decide whether it owns and organizes its own logistics or whether it subcontracts some or all of its logistics to a specialist logistics provider (third party provider, or 3PL). Many large manufacturers use several (up to about 70) 3PLs. Some manufacturers will organize some of their logistics function, but subcontract other elements to specialists.

Over the past decade, there has been a movement toward the use of global logistics companies, such as Schenker, DHL, UPS, and Fedex. This is largely because production, consumption and trade has become more globalized. Global trade has increased the need for such mega-logistics companies but, in turn, the development of such companies has facilitated and enabled the globalization of trade. They basically promise delivery of any goods anywhere and achieve this through partnerships with local companies, as well as through the ownership of global logistics facilities.

Goods to be transported can be categorized into raw materials, semifinished products, finished products, and consumer products, or sometimes referred to as business-to-business (B2B) goods and business-to-consumer (B2C) goods. At a company level, logistics can be further categorized by dividing into “upstream” and “downstream,” where upstream refers to the logistics involved in getting goods to the company (which may involve the organization of many different inputs and companies) and “downstream” involves the logistics of getting goods from the company to the consumer (which could be another producer). Equivalently, these may also be referred to as “primary” and “secondary” logistics or “supply side,” and “demand side” logistics.

In the past, manufacturers and retailers worked on a “push” basis, where demand was forecasted and goods were produced/supplied based on these forecasts. Nowadays, most manufacturing/retailers work on a “pull” basis, where consumers buy products

Figure 7 Transport of goods on countries' territory by type of transport in 2017 (million tons). *Source: From Eurostat (2019b)*

and this purchase triggers a “pull” for more of the product to be supplied/manufactured. The use of IT and digitalization has greatly facilitated this trend. The outcome is that inventory has been reduced and less waste is produced. “Just-in-time” and “lean” logistics have evolved to deal with this change. It remains to be seen how future systems and innovations, such as block chain technology for example, will impact worldwide logistics practices and freight transportation in particular.

Biographies

Sharon Cullinane is Professor of Sustainable Logistics at the University of Gothenburg Business School. Having gained her PhD in logistics from Plymouth University in 1987, she has lectured, researched, and published in the field of transport policy and the environment around the world. She has been employed at Heriot-Watt University in Edinburgh, the University of Hong Kong, Oxford University, the Egyptian National Institute of Transport, the Ecole Supérieur de Rennes, and Plymouth University. For many years she has been interested in e-commerce and its impact on the environment. Her current research interest lies in the area of returns in the e-commerce sector and its impacts on the environment, focusing particularly on the clothing sector in Sweden. She is also Program Coordinator of the Masters degree in Logistics and Transport Management at Gothenburg University.

Kevin Cullinane is Professor of International Logistics and Transport Economics at the University of Gothenburg. Kevin has been a logistics adviser to the World Bank and transport adviser to the governments of Scotland, Ireland, Hong Kong, Egypt, Chile, and the United Kingdom. He holds an Honorary Professorship at the University of Hong Kong and is a Visiting Professor at the VTI (the Swedish National Road and Transport Research Institute), Liverpool John Moores University, Dalian Maritime University, and Shanghai Maritime University. Prior to joining the University of Gothenburg on a permanent basis, he was appointed to the lifetime position of Honorary Visiting Professor at the University. Kevin has personally won research and consultancy projects to the value of \$US 6.5 million, many of which have informed the policies of national and/or regional governments. He has held other positions as the Director of the Transport Research Institute (TRI) at Edinburgh Napier University, Chair in Marine Transport & Management at Newcastle University, Professor and Head of the Department of Shipping & Transport Logistics at Hong Kong Polytechnic University, Head of the Centre for International Shipping & Transport at Plymouth University, Postdoctoral Research Fellow at the University of Oxford Transport Studies Unit and as Senior Partner in his own transport consultancy

company, based in Cairo, Rennes, Hong Kong, Edinburgh and now Gothenburg. Kevin has published 14 books and over 300 journal papers and is an Associate Editor of *Transportation Research D*, *Maritime Economics & Logistics* and the *International Journal of Applied Logistics*. He is also a member of the Editorial Boards of *Transportation Research A*, *Transport Reviews*, the *Annals of Maritime Studies*, the *Journal of Shipping & Logistics* and, formerly, of the *Proceedings of IMechE Part M: Journal of Engineering for the Maritime Environment* and the *International Journal of Logistics Management*. Kevin has been a Chartered Fellow of the Chartered Institute of Logistics & Transport since 1997. His expertise has been recognized at UK national level with his appointment to REF 2014 and REF 2021; the United Kingdom's national research evaluation exercise.

Introduction

Logistics and supply chain management have traditionally focused on the acquisition, manufacture and delivery of goods to consumers. These capabilities traditionally evolved from military applications but expanded significantly for use in more broad commercial settings. Historically, the capabilities have been grouped into the functions of purchasing, production, and logistics. The traditional focus has been on optimizing the performance of these functions. For example, purchasing, production and logistics decisions were made to minimize the expenses within their own operations.

More recently, firms have shifted their focus from functional to integrated process. The integrated process emphasizes the combination of functions and activities that must be coordinated to deliver value to customers and consumers. **Table 1** lists and describes the processes. The concept behind a process is a group of activities that use the functional resources (inventory, production equipment, transportation equipment, technology, etc.) to provide value to customers. In most cases, the processes closely match with organizational components of the firm, including product development/launch, purchasing, production, logistics, and post-sales support.

Table 1 Supply chain processes

Process	Description
Demand planning responsiveness	The assessment of demand and strategic design to achieve maximum responsiveness to customer requirements.
Customer relationship collaboration	The development and administration of relationships with customers to facilitate strategic information sharing, joint planning, and integrated operations.
Order fulfillment/service delivery	The ability to execute superior and sustainable order to delivery performance and related essential services.
Product/Service development launch	The participation in product service development and lean launch.
Manufacturing customization	The support of manufacturing strategy and facilitation of postponement throughout the supply chain.
Supplier relationship collaboration	The development and administration of relationships with suppliers to facilitate strategic information sharing, joint planning, and integrated operations.
Life cycle support	The repair and support of products during their life cycle includes warranty, maintenance, and repair.
Reverse logistics	The return and disposition of inventories in a cost effective, secure, and responsible manner.

Supply Definition and Activities

Due to the many views and perspectives regarding supply chain, there are varying definitions that include different institutions, processes, functions, and activities. As such, there is not one common definition. There is not even a common set of processes or activities that most experts would agree to include. However, it is important that this article establishes a foundation by providing a definition and describes the range of applications for logistics and supply chain management. According to Bowersox et al. (2019), supply chain management is a set of processes to effectively and efficiently integrate suppliers, manufacturers, distribution centers, distributors, and retailers so that products are produced and distributed at the right quantities, to the right locations, and at the right time to minimize system-side costs, while achieving the consumer's desired value proposition.

What began during the last decade of the 20th century and will continue to unfold well into the future can be increasingly characterized as the information-based or digital supply chain. The information or digital enterprise will connect collaborating business organizations to drive a new order of relationships called supply chain management. Managers are increasingly improving and integrating traditional marketing, manufacturing, purchasing, and logistics practices. This information-based evolution has facilitated the development of the supply chain discipline, which can be defined as a coordinated, cross-functional strategy, involving both internal and external partners that utilize process and information to improve operating efficiency and leverage strategic positioning. Supply chain strategy applies the functions and processes to effectively and efficiently integrate suppliers, manufacturers, distribution networks and channels, as well as final consumers, all of which ensures that the firm's value proposition is achieved while minimizing total system cost.

While there are other definitions that come from different perspectives (Institute of Supply Management, Association for Supply Chain Management and Council of Supply Chain Management Professionals), there are common themes that suggest a common framework. These definitions emphasize key concepts including effective and efficient flow, crossfunctional collaboration, collaborative institutional partners, achieving the consumer's value proposition, and minimizing system-wide cost. Efficient and effective flow emphasizes the need for a firm to work collaboratively with other supply chain partners to deliver the product to the consumer at a minimum cost. The crossfunctional collaboration requires that the firm's internal functions, particularly those involved in the supply chain, work together to minimize waste and the duplication of time and resources. Achieving the consumer's value proposition means that the supply chain can deliver the product or solution in a form that can meet the unique consumer requirements. Finally, "deliver at minimum cost" means that the firm and its supply chain partners try to deliver the product or solution to the consumer while minimizing the total end-to-end cost for all activities occurring in the supply chain.

With this process perspective as background, my experience as the chairperson of the Department of Supply Chain Management at Michigan State University suggested a broader range of applications for supply chain principles. This perspective was developed through many conversations with recruiters at MSU. These discussions suggested a wide range of other applications for supply chain principles beyond the traditional product focus. Table 2 lists and describes some of these nontraditional applications.

Why is it important to take this broader perspective? While there are certainly many firms that are primarily concerned with the production and movement of traditional products, there are many more that are interested in these broader supply chain solutions. These other applications suggest many opportunities for supply chain professionals and extend the role that supply chain can have in firm competitiveness. While the typical supply chain is focused on a manufacturer with the support of suppliers, distributors, retailers, and supply chain service providers, there are many nontraditional environments where supply chain principles can be effectively applied.

Although many believe that supply chain principles and practices are primarily relevant for major manufacturing firms, Table 2 demonstrates that the principles can be applied in many other scenarios and environments. It is increasingly common for nonsupply chain executives to reach out to supply chain professionals when they are challenged with problems that have process and resource management characteristics. It is important for supply chain professionals to understand the environments that supply chain principles can be applied to. This insight can also result in a wide range of job opportunities for supply chain professionals and increased influence in their firm.

Extended Logistics and Supply Chain Applications

Whereas supply chain principles can be applied in these broader contexts, there needs to be some context refinements to define specific requirements. These refinements include: (1) service focus; (2) financial focus; (3) procurement focus; (4) manufacturing focus; (5) logistics focus; (6) opportunities for performance enhancement; and (7) product types. Service focus refers to the dimensions of the service requirements desired by customers. Financial focus refers to the benefits desired by the firm, such as profit, return on assets or satisfying humanitarian needs. In the case of procurement, manufacturing, and logistics, the focus would relate to whether the firm should emphasize economies of scale or flexibility. Opportunities for performance enhancement refers to the firm's ability to create competitive advantage using a low cost, service differentiation, or hybrid strategy. Product type refers to the product categories that would be appropriate for each application. Tables 3A–D lists these extended applications and some of the ways that they differ from typical supply chain applications. The follow sections discuss some of these differences.

Table 2 Supply chain applications

<i>Supply chain applications</i>	<i>Description</i>
Product supply chain	Traditional supply chain involving suppliers, manufacturers, distributors, and retailers for consumer products. This is the primary focus of many supply chain operations and most commonly covered in classes and texts.
Promotional supply chain	Supply chain for items that are being heavily promoted such as end-aisle tasting displays in wholesale clubs. The major challenge is that all items related to the promotion (product, utensils, cooking materials, display materials, and demonstrator must be assembled with the cart and delivered to the store to meet the weekend display schedule.
Bulk material supply chain	Supply chains designed to move bulk products such as grains, metals, and chemicals. In many cases, these materials are relatively low value so all movement and handling in the supply chain must take advantage of significant economies of scale and often specialized vehicles.
Talent supply chain	Applying supply chain principles to talent management where individual talent represents the products that are moved through the supply chain with the value-added process being training and education.
Business to consumer (B2C) supply chain	Business to consumer supply chains represents the increasing volume of product that is sold online from manufacturers or distributors directly to consumers.
Recycling supply chain	Supply chains responsible to handle returns for recycling of products, components, reprocessing, and packaging.
Resource supply chain	Resource supply chains are designed to provide facility resources for information-based supply chains such as server farms for cloud or social media applications. This includes the purchasing and sequencing of land, regulatory approvals, utilities, and equipment to provide the technology services.
Construction supply chain	Construction supply chains provide and sequence the equipment, building supplies, and specialized labor for construction.
Recovery supply chain	Recovery supply chains are employed to recover material that has reached its useful life in the field. A recovery supply chain is useful following military, construction, mining, or drilling operations.
Humanitarian supply chain	Humanitarian supply chains provide postevent support for disaster recovery. This includes bring in equipment for recovery, food and medical care items, and commodities to support reconstruction.
Global supply chain	Global supply chains source and deliver from multiple regions around the world. While most supply chains include global aspects, it is important to consider specific global characteristics such as demand variation, distance, and documentation.
Durables supply chain	Durables supply chains are designed to facilitate the handling and delivery of heavy equipment such as agricultural, construction, or military equipment. The major differentiator for durables supply chains is specialized transportation equipment due to infrastructure restrictions.
Agricultural commodity supply chain	Agricultural commodity supply chains move agricultural product from the farm to the commodity elevator or the processing plant. In most cases, the challenge is to move this bulk product economically so the farmer can still make money even when the buyer sets the price. In other words, if the farmer is too far from the buyer, there will have no market for his products.
Innovative supply chain	An innovative supply chain is one that must rapidly introduce new product to the market. This is typically a responsive supply chain that is defined to bring new product variations to market or to have souvenirs such as for movies, athletic events, or customized product introductions available when the event is taking place (e.g., concerts, movies, openings, etc.).
Military supply chain	Military supply chains are designed to support military operations. Specialized requirements include the ability to provide supply chains for a range of products (food, medical, and equipment) in demanding environments (dessert, jungle, and supporting combat operations) under varying requirements for responsiveness.
Clinical trials supply chain	Clinical trials supply chains are designed to support the very precise demands for completing pharmaceutical clinical trials. Clinical trials are very demanding due to the need for precise controls of dosages, ingredient combinations, and drug combinations.

Product Supply Chain

The standard product supply chain demonstrates the flow of product from the raw material provider to the consumer. This is typical of most organizations that manufacture product on a relatively consistent basis without significant seasonal spikes. The classical example is “every day low price.” The service focus is to meet the availability and access requirements desired by the consumer. In general, the financial focus is to grow through increased revenue or market scope. In terms of procurement, manufacturing, and logistics, the primary focus is to take advantage of economies of scale in overall supply chain operations. Typically, the firm’s performance will likely be enhanced through increased volume. The product supply chain is typical for fast moving food and general merchandise.

Promotional Supply Chain

The promotional supply chain demonstrates the flow of products that are pushed at different times during the year through price discounts or advertising. In this case, the product flow, from raw material acquisition through delivery to customer, is seasonal or very spiky. The implication of a promotional supply chain is that it must be flexible because it needs to accommodate significant swings in volume. The primary focus of a promotional supply chain is to meet the sales and revenue objectives of the promotion. In general, a promotion is designed to increase market share by introducing a product to new consumers or to get existing consumers to stock up so they will not purchase competitive products. In the case of purchasing, manufacturing, and logistics, the focus is to be able to acquire, produce, and deliver the product in an environment where there are significant swings in material, production, and

Table 3A Supply chain applications

	<i>Product supply chain</i>	<i>Promotional supply chain</i>	<i>Bulk material supply chain</i>	<i>Talent supply chain</i>
Service focus	Meeting customer service objectives	Meet sales objectives of promotion	Provide service with maximum asset utilization	Provided appropriately trained and experienced personnel
Financial focus	Focus on volume	Increased market share	Take advantage of raw material capacity	Maximize utilization of trained and experienced expertise
Procurement focus	High volume reliable suppliers	Obtain raw materials in volumes to meet specific promotion	High volume reliable suppliers	Shift from fixed to variable cost with high degree of specialization
Manufacturing focus	High volume manufacturing	Customized agile production	Minimize changeovers	Increased application of specialized talent under time constraints
Logistics focus	Economies of scale	Obtain transport capacity to meet volume requirements	Require bulk transport (water, rail, and truck)	Finding talent that can be employed in desired location (language and permits)
Opportunities for performance enhancement	Increased revenue	Increased market share	Move from commodity to specialized	Maximum utilization of specialty talent
Product types	Food and general merchandise	Food and general merchandise. Event related promotions	Petroleum, chemicals, and construction commodities	Research, information technology, medical, and supply chain talent

Table 3B Supply chain applications

	<i>B2C supply chain</i>	<i>Recycling supply chain</i>	<i>Resource supply chain</i>	<i>Construction supply chain</i>
Service focus	Responsive home delivery for significant volume variations	Maximize quantity recycled	Meet solution requirements of consumers	Meet building availability requirements
Financial focus	Increased access to customer base	Minimize cost of recovery	Minimize assets required	Minimize cost of materials and labor
Procurement focus	Increased range of products	Gain access to volume of recyclables	Schedule asset arrival in a timely manner	Trade-off acquisition cost versus storage requirements
Manufacturing focus	Increased customization and breadth of line	Effective process of recyclables to create reusable materials	Parallel processing	Parallel processing and site logistics
Logistics focus	Responsive delivery and low-cost returns processing	Minimize transport cost in noneconomy of scale environments	Arrival sequencing and inventory minimization	Arrival sequencing, inventory minimization, and licensing
Opportunities for performance enhancement	Increased volume over last mile. Processing time and capacity considerations	Easy to disassemble and sort	Take advantage of opportunities for parallel processing	Take advantage of opportunities for parallel processing
Product types	Increasing range of products	Metals, electronics, and durables	Project management and financial documents	Facilities construction

Table 3C Supply chain applications

	<i>Recovery supply chain</i>	<i>Humanitarian supply chain</i>	<i>Global material supply chain</i>	<i>Durables supply chain</i>
Service focus	Return goods for reuse	Search, recovery, and meet critical necessities	Meet unique regional requirements	Meet customer delivery requirements
Financial focus	Reuse assets and minimize cost	While cost is important, perception may be more important	Low total cost including duties and taxes	While it is important, cost is often secondary with more emphasis on solution provided
Procurement focus	Organize items to be recovered	Preposition requirements	Meeting regional and regulatory requirements	Standardize components
Manufacturing focus	Remarketing or remanufacturing	Adapt products to environment	Standardize as much as possible	Extensive variation and complexity
Logistics focus	Adapting to low scale economies	Infrastructure is often limiting	Work within local infrastructure and service providers	Specialized equipment
Opportunities for performance enhancement	Consolidation	Product prepositioning	Apply appropriate global strategy	Collaboration with other firms serving similar customers
Product types	Military, construction, and electronics	Floods, earthquakes, hurricanes, and political uprisings	Durables and furniture	Farm and construction equipment

Table 3D Supply chain applications

	<i>Agricultural commodity supply chain</i>	<i>Innovative supply chain</i>	<i>Military supply chain</i>	<i>Talent supply chain</i>
Service focus	Meet production requirements of production facilities	Make sure product is available when required in desired markets	Meet requirements of war fighters	Very precise delivery to trial patients
Financial focus	Maximum use of commodity priced items	Cost is definitely secondary	Increasingly important	Cost is important but not nearly as important as delivery precision
Procurement focus	Commodity items	Work with suppliers to develop innovative components	Meet Defense Acquisition Regulations System (DFARS)	Meet quality and certification requirements
Manufacturing focus	Maximize productivity for commodity conversion	Pilot plant capability	Make versus buy	Apply quality pilot production capabilities
Logistics focus	Transport cost results in reduced price received by farmer	Precise delivery requirements with security	Non-standard and hazardous goods transportation	Precise delivery is critical
Opportunities for performance enhancement	Reduce transport distance while maximizing scale of production	Specialty innovative supply chain	Apply lessons from commercial sector	Collaboration with competitors involved in clinical trials
Product types	Agricultural commodities	New products	Military consumables and capital goods	Pharmaceuticals involved in trials

delivery capacity requirements. This can typically only be done effectively when capacity requirements can be smoothed out across multiple products. The typical result of promotional supply chains has increased market share and is often used to increase the volume of food and general merchandise products and for special event items.

Bulk Material Supply Chain

The bulk materials supply chain demonstrates the flow of commodity products, such as petroleum, chemicals, and coal, typically from a mine or well to the processing facility. In this case, large volumes are being moved requiring bulk transportation equipment such as pipelines, ships, barges, or rail cars. Due to the product bulk, a significant percentage of the product value is related to transportation, so transport mode is a critical consideration. In terms of purchasing, manufacturing and logistics, product volume and changeovers need to be maximized and minimized, respectively. While these bulk materials/commodities still require economies of scale in processing and transportation, their customers are increasingly looking smaller and more responsive shipments, which is driving them to smaller shipment sizes and more less than truckload transport modes. While bulk materials supply chains are very important, their unique requirements for bulk movement are sometimes not well understood.

Talent Supply Chain

The talent supply chain refers to the application of supply chain principles to talent management and development. In effect, the management and operational talent becomes the product that is moved through talent development stages, such as training and job experiences. Increasingly, human resource management firms are using supply chain principles to manage the individuals, so that their specialized skills can be enhanced and applied. As an example, with the increasing shortage of talent, it is critical that the individuals be provided with the experiences that they need. In an environment where this is a shortage of supply chain managerial and operational talent, the effective development and use of existing talent is critical. Applying supply chain principles to talent management is particularly relevant when there is a talent resource shortage. Supply chain principles are specifically being used to manage specialized talent in the fields of research, information technology, medicine, and supply chain management. The other fields that these principles could be applied in include disciplines, where there is a high degree of specialization, significant benefits of experience, and a shortage of talent. [Kelly OCG \(2017\)](#), a division of Kelly Services, has used supply chain management principles to manage the talent pipeline for many of its clients.

Business to Consumer (B2C) Supply Chain

The B2C supply chain refers to the application of supply chain principles for firms delivering directly to homes. The obvious application is Amazon and similar firms who offer a wide range of items within a delivery time of a few days. Consumers are increasingly requesting this type of agile responsiveness to deliver everything from books to specialized electronics to general merchandise directly to their homes. While some of the items are reasonably expensive and can justify premium transportation, most of them are not, so it is difficult to provide quick delivery without having distribution centers in close proximity. The result is that B2C supply chains typically require many distribution centers with the capability to customize the product. While such last-mile delivery is very expensive, firms are using their last mile delivery capabilities to offer a wider range of products to their consumers,

which will spread the delivery cost over a wider range of products. The result is a supply chain that is agile and responsive focused rather than economies of scale focused.

Recycling Supply Chain

The recycling supply chain refers to a firm's ability to collect and process recyclable material. The major focus is to recover material for remarketing, remanufacturing, or recycling. Remarketing, remanufacturing, and recycling are becoming increasingly important to satisfy a firm's need to meet environmental and sustainability requirements for consumers and regulators. The remarketing application includes the recovery of products such as electronics or office furniture that can be renewed and resold. The remanufacturing application includes the recovery and reprocessing of products such as electronics, office furniture, mechanical components, and packaging. In these cases, the product may be disassembled and then rebuilt using new or renewed components for resale to consumers. The recycling application collects used products and packaging to reprocess them into materials such as metal or plastic. These recycled materials can then be reused to manufacture new product. A recycling supply chain is particularly relevant for materials such as plastics and aluminum. The supply chain challenge for recycling is effectively collecting used materials from consumers and transporting it to a processing facility while achieving some level of scale economies. There are many articles that discuss the nuances of recycling (Shahparvari et al., 2018).

Resource Supply Chain

The resource supply chain focuses on processes that handle products that would not traditionally be considered supply chain products. Examples might include financial or mortgage documents. While these documents may be processed electronically, there is still often a need to move the documents physically through a process with capacity constraints. These constraints might be in the form of equipment or individuals with specialized expertise. As such, this process is not unlike the processing of products through a job shop production facility. The challenge is to design the document flow to take advantage of batch or parallel processing opportunities to optimize the use of constraining resources.

Construction Supply Chain

The construction supply chain focuses on the building of facilities such as houses, commercial buildings, and manufacturing complexes. While construction has not typically been viewed as a supply chain application, a review of the process makes it obvious that any construction initiative requires process and resource management. The resources include not only the construction materials, but also the approvals and regulatory authorizations. The processes include the construction activities and the fact that many of them must be completed in sequence. The combination of constraints regarding site logistics and construction expertise emphasize the importance of effective process and resource management.

Recovery Supply Chain

The recovery supply chain focuses on returning goods for reuse. The typical application of these principles occurs when products are used for an event (construction or military initiative) with the desire to return for reuse. Examples might include construction equipment like earth movers, cranes, material for oil wells, and military equipment, like personnel transporters or tanks. At the completion of such an initiative, there may be a desire to return these goods for reuse or to provide them to another organization. While the goods can sometimes be remarketed or remanufactured, there are often restrictions on how and where the returned goods need to be handled. For example, there are often restrictions where military equipment can be returned and how it must be handled due to the environment it was used in. While the focus should be to take advantage of consolidation opportunities when possible, the challenge is that there are many complexities that must be considered.

Humanitarian Supply Chain

The humanitarian supply chain focuses on products and relief supplies to those who do not have regular access to items like medical supplies or life support materials. The access may be on a regular or emergency basis, such as when medical supplies are not available due to a regular or emergency lack of infrastructure. As an example, it is often the case that it is not possible to get medical, pharmaceutical, water, or food supplies to populations outside of the developed or available infrastructure. The challenge in these situations is to either preposition commodities when possible or utilize alternative modes to overcome the modal limitations. The recent hurricanes and floods have demonstrated the need for these capabilities and the role that they can play in enhancing firm perception.

Global Supply Chain

The global supply chain reflects the need for recognizing the challenges inherent in global operations. While most larger firms operate and understand the implications of operating global supply chains, most smaller firms also operate globally whether they

know it or not. They often have international suppliers and customers that are not visible to them. The result is that such firms do not understand the supply chain differences characteristic of global operations. These differences include distances and time delays, documentation and compliance requirements, technical differences, and population diversity. The overall result is that the global supply chain is substantially more complex. The challenge, then, is that all firms must increasingly become more proactive in understanding the implications and requirements to support global supply chain operations.

Durables Supply Chain

The durables supply chain refers to the challenges related to moving large manufacturing, construction, marine, or agricultural equipment. These durable delivery supply chains are generally unique because they require specialized equipment and, often, infrastructure monitoring to move the finished product. Infrastructure monitoring refers to the need to have tracking vehicles to protect traffic and infrastructure, such as bridges that can accommodate large durable equipment. The products are obviously highly specialized and complex. While cost is a consideration, the primary focus is to complete delivery of the product. Unlike most supply chain applications, durables supply chains are different in that each of them has unique characteristics.

Agricultural Commodity Supply Chain

The agricultural commodity supply chain focuses on the movement of bulk agricultural commodities such as lumber, grains, or soybeans. While agricultural commodity supply chains are similar to bulk material supply chains in that they are typically moved in large loads, there are significant differences in that agricultural commodities must be collected from farms across the geography. The implication is that these bulk shipments are often made on secondary roads, which results in seasonal congestion and road damage. Another issue related to commodities in general, and agricultural commodities specifically, is that the effective selling price of the product to the processor must be reduced by the transportation charges. This limits the distance that the farms can be from the processors and still be competitive. The challenge in agricultural supply chains is to understand the trade-offs related to the location for the demand of processed commodities, the production economies for the processing facility and the source for enough commodity volume to support production. Topics of specific interest for agricultural commodities include food security and flow optimization. Due to the complexity of the food supply chain, there has been an increasing use of optimization and simulation tools applied to identify an integrated solution (Ge et al., 2015).

Innovative Supply Chains

The innovative supply chain focuses on the processes to get relatively low quantities for new product introductions to trial markets. While some firms believe that their supply chain for innovative products is a subset of the supply chain for their standard products, the requirements are actually quite different. As discussed previously, the typical product supply chain has the primary focus on economies of scale, whereas the innovative supply chain should be primarily focused on agility and responsiveness. The innovative supply chain must be able to purchase the raw material in enough quantity to facilitate production of the new product, produce it in what is typically a pilot plant setting, deliver the product in agile fashion to test markets, and provide confidentiality through the entire process to protect competitive advantage.

Military Supply Chain

The military supply chain focuses on one of the oldest applications in the world. Two examples illustrate the role of logistics and supply chain professionals in the military. The first describes the role of logistician in the military: "Logisticians are a sad and embittered race of men who are very much in demand in war, and who sink resentfully into obscurity in peace. They deal only in facts, but must work for men who merchant in theories. They emerge during war because war is very much a fact. They disappear in peace because peace is mostly theory. The people who merchant in theories, and who employ logisticians in war and ignore them in peace are generals. Generals are a happily blessed race, who radiate confidence and power. They feed only on ambrosia and drink only nectar. In peace, they stride confidently and can invade a work simply sweeping their hands grandly over a map, pointing their fingers decisively up terrain corridors, and blocking defiles and obstacles with the sides of their hands. In war, they must stride more slowly because each general has a logistician riding on his back. He knows that, at any moment, the logistician may lean forward and whisper: 'No, you can't do that.' Generals fear logisticians in war and try to forget them in peace. Romping along beside generals are strategists and tacticians. Logisticians despise strategists and tacticians. Strategists and tacticians do not know about logisticians until they grow up to be generals – which they usually do. Sometimes a logistician becomes a general. If he does, he must associate with generals whom he hates; he has a retinue of strategists and tacticians whom he despises; and on his back, is a logistician whom he fears. This is why logisticians who become generals always have ulcers and cannot eat their ambrosia" (Anon, cited in Bowersox et al., 2002, p. 596).

President Dwight D. Eisenhower put it more succinctly when he wrote: "You will not find it difficult to prove that battles, campaigns and even wars have been won or lost primarily because of logistics" (Bowersox et al., 2019, p. 383).

One of the major challenges related to military supply chains is the shift to increased consideration of cost. While kings and generals had traditionally thought that "cost was no object" when providing resources for the military (because the implications of

losing a war were so severe), today's civilian leader knows that military spending does not generate a substantial number of votes. As such, today's military supply chain is becoming more like a commercial supply chain, where there are strong cost considerations. While logistics has historically been the focus of the military, there has been increasing emphasis on a more holistic supply chain consideration, where the military objective is to minimize total supply chain cost (Haraburda, 2016).

Clinical Trials Supply Chain

The clinical trials supply chain focuses on the processes and flows to support the regulatory trials of prescription pharmaceuticals. These extensive trials must be conducted with a controlled sample of patients prior to making the drugs available to the general population. The supply chain challenge for clinical trials is that the sample products (both those with the active ingredients to be tested and those that are placebos (no active ingredients) must be manufactured and distributed in a very controlled manner to the test patients. The unique characteristic of clinical trials is that the different types of products must be tracked and recorded very accurately to ensure that the result statistics are accurate. Any accuracy or delivery failures could invalidate the trials and require the pharmaceutical firm to begin the trials over again. There are very few other applications, which require such a high level of supply chain precision and consistency.

Conclusion

Opportunities for the application of supply chain principles are increasing dramatically. However, many supply chain professionals tend to limit their scope when considering where their expertise and skill can be applied. Based on years of interactions with students and recruiters, it became clear that there was a need to identify and describe the broader range of applications so that nonsupply chain professionals can identify the potential benefits and supply chain professionals can identify the opportunities.

Introduction

The phrase that “you can’t manage what you can’t measure” is attributed to various sources and has become an important business aphorism. There are two additional, related quotes that highlight today’s preoccupation with performance measurement and key performance indicators (KPIs). The management guru Peter Drucker argued that “if you can’t measure it, you can’t improve it,” while the statistician and quality control expert W. Edwards Deming suggested that “in God we trust, all others bring data.”

These three concepts are very applicable in the logistics and supply chain management (SCM) domains where organizations are concerned with what have been called the “7 rights:” the right product in the right place at the right time to the right customer in the right amount or quantity in the right condition and at the right cost. These “rights” are predicated on being able to measure what goes into a logistics and SCM process and, more importantly, tracking and tracing where goods, products, or services are in that process.

This chapter provides an overview of logistics and SCM performance measurement in three sections. First, performance measurement and measures or metrics in general are discussed regarding current practice and provide suggestions for managers on selecting appropriate measures for the organizations. Then, different types of performance measurement frameworks are introduced regarding management of performance measurement and measures. Finally, two special contexts, sustainable or environmental and humanitarian logistics and SCM, are presented to consider nuances on usual organizational performance measurement and include the use of two frameworks, the Balanced Scorecard (BSC) and the Plan-Do-Study-Act (PDSA) cycle, to illustrate these nuances.

Performance Measurement and Measures

Performance measures (PMs) are a set of metrics or measures used to quantify the efficiency and/or effectiveness of an action. PMs enable an organization’s mission or strategy to be translated into reality by generating “actionable” knowledge that is essential for managing and navigating organizations through turbulent and competitive global markets. They allow organizations to track progress against their strategy, identify areas of improvement and act as a good benchmark against competitors or industry leaders. The information provided by PMs allows managers to make the right decisions at the right times.

One of the most prevalent issues associated with performance measurement is having too many metrics. Some organizations are using hundreds of metrics, which are often not aligned to the organization’s strategy. One review of logistics and supply chain performance measures by identified almost 90 metrics, of which 40% were financial and 60% were functional (Shaw, 2013). Such metric proliferation can lead to confusion, often results in “paralysis by analysis” and presents difficulties in conducting benchmarking exercises. Thus, organizations need to determine a meaningful but parsimonious set of PMs, so they can be effectively implemented and monitored.

Table 1 Common logistics and SCM performance and service measures

Accurate invoices
Accurate orders
After-sales support
Appropriate order cycle time
Availability of products
Complete orders
Consistent order cycle time
Consistent product quality
Customized services
Delivery time
Helpful customer service representatives
On-time delivery
Products arrive undamaged
Products arrive to specification
Supplier commitment
Supplier integrity
Supplier trust

Table 2 Eight criteria for judging performance measures

Criteria	Description
Validity	PM accurately captures activities being measured and controls for any external factor
Robustness	PM can be interpreted similarly by users, is comparable across time, location and organizations, and is repeatable
Usefulness	PM is readily understandable by managers and provides a guide for action
Integration	PM includes all relevant process aspects and promotes coordination across functions and organizational units
Economy	PM benefits are greater than the costs of PM data collection, analysis and reporting
Compatibility	PM is compatible with existing information, material and cash flow systems in the organization
Level of detail	PM provides enough degree of granularity or aggregation for the user
Behavioral soundness	PM minimizes incentives for counter-productive acts or game-playing and is presented in a useful form

Source: Compiled from [Caplice and Sheffi, 1994](#)

Traditionally, logistics and supply chain PMs have been quantitative and orientated around measuring cost, time, and accuracy. For example, order lead-times, delivery performance, customer query time, and total cash flow time within a framework of strategic, tactical, and operational performance levels. [Table 1](#) lists, in alphabetical order, almost 20 PMs related to logistics and SCM functions and service previously documented by [Grant \(2012\)](#). While some may appear to be the same, there are nuances as to their meanings for individual or focal organizations.

For example, appropriate order cycle (or lead time) may be what a supplier can offer in terms of delivery dates, that is, 3 weeks or 3 days. The product type, whether it is perishable, and final demand from the focal organization's customers will be important factors in determining the appropriate order cycle. Consistent order cycle time is the variance around the appropriate order cycle time, for example, 3 weeks $\pm$ 4 days. Focal organizations are also concerned with this element, as too great a variance can affect their own scheduling and planning.

Thus, a key challenge for organizations is to determine and select the most appropriate and effective PMs. Managers should continually review and evaluate these PMs to make sense of the large number of metrics available and to ensure they reflect the ever-evolving business environment. [Table 2](#) presents eight criteria from [Caplice and Sheffi \(1994\)](#) for judging the quality of PMs or metrics, as they relate to an organization's strategic objectives and strategies and considering its external environment. Managers can use any or all of these criteria to assess any PMs they would consider choosing. However, once the appropriate PMs are chosen, the next step is to embed them into some form of performance measurement framework or system. The further section discusses this topic.

Performance Measurement Frameworks

Over the last 40 years, researchers have proposed various performance frameworks to manage firm performance, including a performance measurement matrix, performance pyramid, performance prism, the BSC, Deming's PDCA cycle, and the supply chain operations reference (SCOR) model in a logistics and SCM context. This has also led to confusion for managers over which framework may work best for their organization and how it should be developed and deployed. Due to space limitations in this chapter we focus on two that are demonstrated in the following section.

The Balanced Scorecard (BSC)

The BSC is a strategic planning and management system that organizations can use to communicate what they are trying to accomplish; align the day-to-day work that everyone is doing with strategy; prioritize projects, products and services, and measure and monitor progress toward strategic targets. The BSC suggests the organization takes a view from four perspectives and develops objectives, measures (KPIs), target, and initiatives (actions) relative to each of these points of view, which are:

- *Financial*, often renamed stewardship or another more appropriate name in the public sectors, this perspective views organizational financial performance and the use of financial resources;
- *Customer/Stakeholder*, this perspective views organizational performance from the point of view of the customer or other key stakeholders that the organization is designed to serve;
- *Internal process*, this perspective views organizational performance through the lenses of quality and efficiency related to its products, services, or other key business processes; and
- *Organizational capacity (formerly called Learning and Growth)*, this perspective views organizational performance through the lenses of human capital, infrastructure, technology, culture, and other capacities that are key to breakthrough performance.

The BSC has been adapted for use by different organizations in different contexts, including logistics and SCM. Although pioneering and popular, the BSC was originally devised by Kaplan and Norton (1992) and thus it is over a quarter of a century old. Criticisms of the BSC and its applications are that it excludes the ability to manage sustainable or environmental performance within an overall business strategy, as well as the people and suppliers who are key stakeholders in the sustainable or environmental management process. The BSC is also a static tool and does not have a dynamic “cause and effect” evaluation loop process and, thus, has no ability to guide businesses through change, which is of central importance to PM. Further, there is a lack of evidence to suggest that the application of BSC improves performance. Finally, extensions to the BSC to incorporate sustainable or environmental PMs have been advocated but not extensively studied, and there are some arguments suggesting that adding sustainable or environmental elements to the BSC might overcomplicate it.

The Deming Plan-Do-Study-Act (PDSA) Cycle

The PDSA cycle is a systematic process for gaining valuable learning and knowledge for the continual improvement of a product, process, or service. Also known as the Deming cycle, or Deming Wheel (Deming, 1950), this integrated learning–improvement model was first introduced to Deming by his mentor, Walter Shewhart of Bell Laboratories in New York (Shewhart, 1939).

The cycle begins with the Plan step. This involves identifying a goal or purpose, formulating a theory, defining success metrics and putting a plan into action. These activities are followed by the Do step, in which the plan components are implemented, such as making a product. Third is the Study step where outcomes are monitored to test the validity of the plan for signs of progress and success, or problems and areas for improvement. The Act step closes the cycle, integrating the learning generated by the entire process, which can be used to adjust the goal, change methods, reformulate a theory altogether, or broaden the learning–improvement cycle from a small-scale experiment to a larger implementation Plan. These four steps can be repeated over and over as part of a cycle of continual learning and improvement.

Another variant is the Plan-Do-Check-Act (PDCA) cycle. Although PDSA and PDCA are often confused and used interchangeably, there are important differences. The main difference is that PDSA attempts to study the consequences of the applied changes more closely and in more detail compared to PDCA. The meaning of the Check step often entails running some basic tests to ensure that the new state of the system corresponds to some baseline measurements. However, that may be insufficient to understand the entire situation and ensure that changes will lead to long-run improvement. Deming emphasized the PDSA cycle, not the PDCA cycle, as he found the focus on the Check step is more about implementation of a change, with success or failure followed by needed corrections to the Plan in the event of failure. His focus was on predicting results of an improvement effort, studying these results, and comparing them to possibly revise theory. He stressed that the need to develop new knowledge from learning is always guided by a theory.

Some authors note that PMs tend to be retrospective, inward looking, not aligned to business strategy, and focused too much on cost as a primary measure. As a result, organizations need to continually review and renew their PMs to ensure they meet the organization’s needs and changing business environment. Further, the development and evolution of PM research has reached a critical point and is entering a new phase or direction, categorized by context, theme, and challenge. The following section considers two special cases of sustainable and humanitarian logistics and SCM.

Special Cases

Sustainable or Environmental Performance Measures

Organizations are facing increased pressure from the government, customers, and competition on their environmental and social performance. Since the beginning of this Millennium, organizations have been looking to quantify and mitigate their impact on

Table 3 Sustainable logistics and SCM performance measures

Electricity consumption measures
Driver behavior for telematics
Carbon dioxide emissions of an activity (route/product)
Carbon dioxide emissions per item/case/pallet delivered
Overall company carbon footprint measures
Vehicle mileage measures
Packaging consumption/reduction measures
Fuel consumption measures
Number of pallet movements or touches per delivery
Utilization/consolidation measures (warehouse/back haul/pallet occupancy)
Fuel consumed per item/case/pallet delivered
Vehicle running costs
Waste recycling measures/reduction/percentage to landfill
Warehouse efficiency measures
Water consumption measures
Gas consumption measures
Overall supply chain carbon footprint measures
Vehicle fill/utilization measures to reduce empty running
Energy used per item/case/pallet delivered
Greenhouse gas emissions (carbon dioxide, nitrous oxide, sulfur, methane, etc.)
Employee environmental or sustainability training
Container size/fill/movements (number of TEUs)
Employee travel (e.g., company car mileage, car share, and cycle to work schemes)
Resource efficiency (raw materials, asset utilization)

Source: Compiled from Shaw, 2013

natural environment ecosystems that contain, inter alia, air, water, and land without which these ecosystems would not exist. Society and humans are both a participant in, and exploiter of, the natural environment and society's use of the natural environment's resources to produce economic goods, products, and services can upset a fragile balance.

Logistics and SCM present a major challenge to the sustainability of these ecosystems in the way that goods and products are transported, handled, stored, manufactured, and supplied throughout the world. For example, fresh air and excess packaging are shipped, with empty return loads, products sit idle and become obsolete in warehouses, and unnecessary products move backward and forward. Supply chain networks are not robust, and innovation is thwarted as every organization works to achieve targets within their own corporate silos, all of which has an impact on natural environment ecosystems. It is important, therefore, for organizations to be able to measure this environmental impact and reduce, mitigate or eliminate it.

As discussed previously, logistics and SCM performance measurement is difficult due to the numerous tiers and echelons found within supply chains and networks and is more difficult in a sustainable or environmental context, due to its increasing importance. A major barrier to the adoption of sustainable PMs is financial, due to the large upfront investment required that results in low adoption rates. Organizations are also confused over what to measure and how to do so. There is a challenge in convincing organizations to invest in sustainability and determining if it is worthwhile. There is also a challenge in assisting organizations to find the most appropriate sustainability measures, especially in a logistics and SCM context. Shaw (2013) developed a list of over 20 logistics and SCM sustainable PMs (Table 3), through research with members of the UK's Chartered Institute of Logistics & Transport (CILT).

Given the nature of the research sample, many of these PMs are transport- and storage-related and, thus, the list in Table 3 is not exhaustive. However, it provides organizations with possible sustainability or environmental PMs in these functions and includes aggregate (e.g., carbon dioxide emissions of an activity) and granular (e.g., carbon dioxide emissions per item/case/pallet delivered) measures. An organization can examine their own logistics and SCM activities to develop a similar list of possible measures that can be reduced to those that directly affect the organization's performance. The next step is to consider what performance measurement framework would best suit that parsimonious list.

Sustainable or Environmental Performance Measurement Frameworks

Some authors have identified that the types of sustainable PMs used are reflected by an organization's evolutionary stage in the sustainable management process. One of the key issues related to the number of current sustainable metrics, which range from air emissions through to water usage. Accordingly, there is a requirement to conceptualize a sustainable and environmental performance measurement system and its requirements, in order to address both this complexity and the volume of metrics and to provide a way forward for the organization.

Figure 1 A Deming PDSA cycle framework for sustainable performance measurement. *Source: Adapted from Hervani et al., 2005.*

Fig. 1 presents an adapted PDSA cycle framework proposed by Hervani et al. (2005) for determining PMs based on the ISO 14001 family of environmental performance management systems to help design, evaluate, and adapt sustainable PMs for logistics and supply chain applications.

Interorganizational performance management systems play an important role in this framework, since organizations are required to explicitly consider the environment in their strategic and operational planning and execution, particularly across their logistics and supply chain activities. This framework can be managed through actions of vertical integration of governance and horizontal integration of internal and external stakeholders.

These actions are required to ensure the structure and functioning of a natural system is protected and maintained, while at the same time providing the goods, products, services, and benefits required by society. Such frameworks have yet to fully exist and operate across many organizations. However, their development and introduction is inevitable as further integration and pressures cause organizations to seriously consider them for their long-term well-being. One way to enhance or enable a framework can be to align it with an environmental or sustainability management certification or accreditation scheme.

Sustainability or Environmental Management Schemes for Logistics and SCM

Sustainable PMs in the logistics and SCM domain have largely focused on greenhouse gas emissions, due to their importance in the fight against climate change. For example, the 2015 COP 21 Paris agreement legally bound industrialized nations to limit temperature rises to below 2°C. However, organizations are also starting to more seriously consider broader sustainable management issues, not only from a mitigation and legislative perspective but also from an adaptation perspective. Consequently, several sustainability and environmental certification or accreditation schemes have been created and developed to assist organizations in establishing and managing their sustainable performance initiatives.

Such schemes range in scope from generic business certifications that assess environmental performance, such as the International Standards Organization's ISO 14000, which specifies a process for controlling and improving an organization's environmental performance, and the European Commission's Eco Audit and Management Scheme or EMAS, developed by the European Commission for organizations to evaluate, report and improve their environmental performance. There are also more industry-specific certifications such as the UK's Building Research Establishment Environmental Assessment Method (BREEAM) which measures sustainability in the building and construction sector, or the Electronic Product Environmental Assessment Tool (EPEAT), an environmental product ratings service that makes it easy to select high-performance electronics that support organizations' information technology (IT) and sustainability goals.

However, this diversity of certifications presents additional challenges for organizations when selecting the most appropriate certification due to the differing scopes and levels each certification may have; such as country, industrial sector, type of organization, type of supply chain, and/or global presence. Most sustainability certifications and standards currently available are voluntary, except for country-specific government acts such as the UK Climate Change Act. However, a significant number of

Table 4 Ten criteria for the sustainable or environmental management of natural ecosystems

Socially desirable/tolerable	Sustainable management PMs are required or understood by society as being required.
Ecologically sustainable	Sustainable management PMs will ensure the safeguarding of fundamental ecosystem features, functions and final ecosystem services.
Economically viable	A cost-benefit assessment of the sustainable management PM indicates economic or financial viability and sustainability.
Technologically feasible	Methods, techniques and equipment for ecosystem and society/infrastructure protection are available.
Legally permissible	Regional, national or international agreements and/or statutes are in place to enable and/or force sustainable management PMs.
Administratively achievable	Statutory bodies such as governmental departments and environmental protection/conservation bodies are in place and functioning to enable success.
Politically expedient	Management approaches and philosophies are consistent with prevailing political climates and have the support of political leaders.
Ethically defensible	Costs to act are determinable and calculable for current and future generations.
Culturally inclusive	Cultural considerations are included in required sustainable management PMs.
Effectively communicable	Communication is effective all stakeholders to achieve the vertical and horizontal integration encompassed in the foregoing criteria.

Source: Compiled from Grant and Elliott, 2018

voluntary schemes are audited to ensure organizations that use and advertise the standards comply with them, for example, the ISO series of standards.

Integrated sustainable management requires combining many aspects into a holistic natural ecosystem and problems caused by materials (e.g., pollution) or infrastructure added to or removed from the ecosystem (e.g., aggregates) require a risk assessment framework to be considered in conjunction with sustainable PMs. Consideration of interactive sustainable or environmental relationships, as discussed previously, and their inherent risks gives rise to assessing whether the strategy or strategic option fulfils various criteria related to sustainable or environmental management.

Table 4 presents ten criteria for sustainable or environmental management discussed by Grant and Elliott (2018) which should be largely fulfilled to ensure that the management of, and solutions for, an environmental problem will be sustainable, successful, and acceptable to society. As such, they should fall within what is realistically possible by encompassing socioeconomic and governance aspects noted in Fig. 1. Fulfilling them would potentially be seen by wider society as achieving sustainability and, in turn, would be more likely to be accepted, encouraged, and successful.

Humanitarian Logistics and SCM

Fast-onset humanitarian crises, such as natural disasters or conflicts, have their own impact regarding appropriate PMs to use and inherent trade-offs affecting usage. In a humanitarian crisis, a very important logistics and SCM consideration is to establish a transport network to provide aid tailored to fit that crisis. The network may be considered as a conduit running from a donor country's port of origin all the way to warehouses or distribution centers (DCs) in or near the affected areas. The network will often pass across an ocean arriving at a discharge port in the destination country or a country near to the destination, but may also pass enroute through warehouses or DCs on land, and be served by rail, road, air, and even barge.

In a crisis situation, humanitarian organizations look to ensure this transport network is up and running quickly, to establish it as robust as circumstances dictate so that supply interruptions do not occur and, while satisfying these objectives, attempt to keep network operating costs to a minimum. Hence, PMs for this situation may not be as determinable or efficient as they would be for a normal business organization, due to the immediacy of need and the life or death consequences for beneficiaries or recipients of aid. Humanitarian organizations will thus need to evaluate several shipping parameters or PMs to distinguish between transport carriers, which will vary by country and type of humanitarian crisis, as part of their carrier selection process. **Table 5** lists a number of these parameters in no particular order (Banomyong and Grant, 2016).

While many of these parameters appear "normal" in the context of business situations, they will be affected by the temporal and fulfilment requirements of ensuring beneficiaries achieve aid goods, products, and services, and hence cost may be less important. However, whatever is saved on transportation cost can be spent on vital aid supplies. The decision as to whether to charter a ship or to place cargo on a liner ship is one example of this trade-off. The World Food Program (WFP) has estimated that transporting aid on liners typically costs between two and twenty-one times as much as on ships chartered by the WFP. Consequently, to keep expensive liner shipments to the minimum, WFP has intensified their efforts to consolidate consignments into larger quantities, suitable for charter vessel carriage.

Another issue is what type of PM framework to use given various interrelationships between several humanitarian organizations and, of course, aid recipients. One attempt has been made to use a modified BSC by Widera and Hellingrath (2016) as shown in Fig. 2.

The BSC has been modified for specific humanitarian operations to reflect the daily tasks of various organizational units involved. Each operation is unique, has different challenges and set-ups, the importance of PMs or KPIs is not the same and several

Table 5 Transport carrier selection criteria for humanitarian logistics and SCM

Geographic coverage of the transport carrier, i.e., local or world-wide
Volume, weight, value and type of aid goods the carrier can handle
Any consignment, load and dimension limits
Transit time from door-to-door
Carrier reliability versus risk
Cost for throughput, distance, time per aid goods “unit” moved
Service frequency and schedule flexibility
Carrier’s service range and choice including the use of technology
Any intermediate handling and/or alternative routings

Source: Compiled from *Banomyong and Grant, 2016*

**Figure 2** A humanitarian logistics and SCM balanced scorecard. Source: Adapted from *Widera and Hellingrath, 2016*

may be conflicting, the organizational stages involved may have different objectives and operate under varying circumstances, and the functioning of the BSC requires understanding and support by all personnel involved. *Banomyong and Grant (2016)* identified ten generic objectives or PMs/KPIs unique to humanitarian operations: responsiveness and speed, cost efficiency, standardization, innovation, co-operation, satisfaction of donors and beneficiaries, reliability, flexibility, inventory performance, and bottleneck management.

Three of the BSC elements, financial, process, and organizational capacity, are well known from the classical BSC. However, the introduction of the network element emphasizes the performance of collaboration with external stakeholders in the humanitarian supply chain. Also, an adjustment for the humanitarian context is the replacement of the customer by the “beneficiary and donor” as it is difficult to transfer the concept of a customer to a humanitarian context. The authors addressed this issue by integrating all beneficiary and donor-related KPIs, partly conflicting and partly conforming, into one perspective to adjust the balance between the respective interests.

The advantage of this humanitarian BSC framework is that the different perspectives allow role-based monitoring in terms of both functions and data aggregation levels that consider a decentralized organization structure that is usual practice, i.e. with headquarters and field offices. Thus, performance levels achieved by the different perspectives can be balanced with regards to organization and operation-specific objectives.

Conclusion

Performance measurement is important for organizations to determine how they are meeting their strategic objectives, particularly about their logistics and SCM activities. This chapter could only provide an overview of this topic to guide readers, especially organizations.

Two key elements were presented in this chapter. First, organizations must determine which PMs are applicable and appropriate for monitoring and control. They should naturally devolve from the organization’s strategic objectives. However, as discussed in the special case of sustainable or environmental measures, some reflection and research may be required to ensure they are correct and meet the eight criteria for an appropriate measure.

Second, the selection of an appropriate performance measurement system or framework is important, in order to best use the selected PMs. Several were presented and details on two of the most popular frameworks, the BSC and Deming’s PDCA cycle, were discussed in more detail and their use demonstrated in the two special cases of sustainable or environmental and humanitarian logistics and SCM, which were provided to illustrate issues outside normal business performance measurement.

Biographies

David B. Grant is Professor of Supply Chain Management and Social Responsibility at Hanken School of Economics in Helsinki, Finland. His doctoral research at the University of Edinburgh investigated customer service, satisfaction, and service quality in UK food processing logistics and received the *James Cooper Memorial Cup PhD Award* from the Chartered Institute of Logistics and Transport (UK) in 2003. David's research interests include logistics customer service, satisfaction, and service quality; in-store and online retail logistics; reverse, closed-loop and sustainable logistics; and humanitarian and developmental logistics. He has over 250 publications in various refereed journals, books, and conference proceedings and is on the editorial board of seven international journals. In 2019 David was ranked 5th in *Economics, Business and Management* and 1st in *Industrial Economics and Logistics* in an academic study determining the "top ten professors in Finland" for research impact and productivity and awarded the *Bualuang ASEAN Chair Professorship* for 2019–21 at Thammasat University in Bangkok, Thailand.

Dr Sarah Shaw is Senior Lecturer and Program Director in Logistics and Supply Chain Management at the Hull University Business School, UK. Her PhD thesis investigated environmental supply chain performance measures. Her research interests include green and sustainable logistics, closed-loop supply chains and performance measurement and reporting. She won "Leader of the Year" in the Women in Logistics Awards, 2017 UK for her work with the Chartered Institute of Logistics & Transport UK encouraging young people to work in the logistics sector. She leads various multi-disciplinary research projects and has published in a variety of scientific journals. One of her publications was selected by Emerald Group Publishing to appear in *A Focus on Sustainable Supply Chains and Green Logistics*, part of "Emerald Gems," which brings together some of the most highly cited, read, and innovative research in its field.

Introduction

Freight transportation is a service that provides for the movement of goods from one place to another place. Freight transportation decision-makers include: (1) providers of freight transportation service, (2) users of freight transportation service, and (3) government (Talley, 1983). If the unreliability of the transportation of goods within a country by privately owned freight transportation firms is negatively affecting the country's economic growth, for example, the country's government may seek to address this slow-growth-economic problem by economically regulating its privately owned freight transportation firms, that is, by regulating certain economic behaviors of the firms as found in Section "Economic Regulation." US laws that economically regulate US freight railroads and US truck carriers are discussed in Sections "Economic Regulation of US Freight Railroads" and "Economic Regulation of US Truck Carriers," respectively.

The economic deregulation by government of a country's economically regulated transportation firms is discussed in Section "Economic Deregulation," followed by discussions of the economic deregulation of economically regulated US freight railroads and US truck carriers in Sections "Economic Deregulation of US Truck Carriers" and "Nationalization," respectively. The privatization of a country's nationalized freight transportation firms by government is discussed in Section "Privatization."

Economic Regulation

Economic regulation is the imposition of rules by government to modify economic behavior.

The economic regulation of privately owned freight transportation firms by a country's government includes rate, entry, service, and financial regulations (or rules) to modify the economic behavior of the firms (Talley, 1983, p. 41).

Rate Regulation

A rate is a price charged by a freight transportation firm in the provision of a freight transportation service. Rate regulation of a freight transportation firm encompasses both the firm's *level of rates* and its *rate structure*. The *level of rates* controls to some extent the firm's earnings, that is, "rates should be established for a regulated firm so that such rates yield no more than a fair return on a fair value of the property committed to public use . . . or earnings high enough to compensate for risk" (Davis et al., 1975, p. 42). The rate structure addresses the specific rates to be charged, that is, the rates should be nondiscriminatory rates where

discrimination is defined as the “use of different rates under similar circumstances or similar rates under different circumstances” (Davis et al., 1975, p. 117).

Entry Regulation

Regulating the entry of freight transportation firms into geographical areas (or on given routes) for the provision of freight transportation services is concerned with how many freight transportation firms should be allowed to compete in given areas (or on given routes). Specifically, the concern is that the entry of new freight transportation firms in given areas (or on given routes) might have negative impacts on the operations of existing transportation firms that are competing in the areas (or on the routes).

Service Regulation

Once an economically regulated transportation firm has been given the authority to operate exclusively in a given area, the quality of the transportation service that it provides in the area may deteriorate over time from the lack of freight transportation competition. This possibility is addressed by government economically regulating the transportation services provided by the freight transportation firm, that is, by government imposing “three general service requirements on the regulated freight transportation firm: 1) to serve, 2) to deliver and 3) to avoid discrimination” (Talley, 1983, p. 52). The requirement to serve requires the freight transportation firm to serve all who request its services. The requirement to deliver requires the freight transportation firm to deliver freight to the consignee in the same physical condition as received from the shipper and with dispatch. The requirement to avoid discrimination requires that both preferential and prejudicial discrimination by a freight transportation firm be avoided between origin-destination points and among classes of freight.

Financial Regulation

The financial regulation of a freight transportation firm consists of government regulating various financial aspects of the firm such as mergers and insurance. The rationale for controlling mergers and requiring that certain types of insurance (e.g., liability insurance) be held by the economically regulated freight transportation firm is that the firm might endanger itself financially, for example, from mergers and not having certain types of insurance, such as liability insurance, when service accidents occur.

Economic Regulation of US Freight Railroads

The industrialization of the US economy grew rapidly following the end of the US Civil War (in 1865) with the growth of the US railroad industry being the driving force. In 1887, the US Congress responded to the US railroad industry having indulged in business malpractices by passing the Interstate Commerce Act of 1887 that established the economic regulation of US freight railroads engaged in interstate commerce. The Act also sought to protect the public against railroad discrimination and other monopoly-related abuses.

The Interstate Commerce Act of 1887 also established the federal regulator agency, the Interstate Commerce Commission (ICC), to monitor US freight railroads to ensure that they complied with ICC regulations. The ICC had the authority to: (1) establish maximum, minimum, and actual rates to be charged by ICC-regulated freight railroads and (2) control the entry of new freight railroads and changes in the operating structures of existing US freight railroads. The ICC-regulated railroad service is to: (1) ensure that adequate rail service is provided to the public, (2) prevent unjust discrimination in service provision by requiring railroads to have adequate facilities and equipment, and (3) control the abandonment of rail tracks. Financial regulation of US railroads by the ICC included: (1) prescribing the accounting systems to be used by regulated railroads and (2) controlling whether a railroad could issue bonds and capital stocks and whether railroads can merge.

Economic Regulation of US Truck Carriers

The US Motor Carrier Act of 1935, an amendment to the US Interstate Commerce Act of 1887, gave the ICC the authority to economically regulate US truck transportation carriers involved in interstate commerce. The 1935 Act classified ICC truck carriers into two categories: (1) common truck carriers that provided transportation service to the general public and (2) contract truck carriers that held contract agreements with a limited number of customers for the provision of truck transportation service.

ICC truck carriers are required by the Interstate Commerce Act to adhere to a “public convenience and necessity” clause, that is, serve a useful public purpose, be responsive to public demand, and operate the service without endangering or impairing the operations of other existing companies. The 1935 Act also required that rates charged by ICC truck carriers be “just and reasonable” and “not discriminate between customers of similar circumstances” (<https://object.cato.org/sites/cato.org/files/pubs/pdf/pa012.pdf>).

Economic Deregulation

Economic deregulation (also known as economic regulatory reform) of an economically regulated industry is the process by which government removes the economic regulation of the industry by removing (in part or in total) the rules that government had placed on the industry in the past in its economic regulation of the industry.

US Freight Railroads

During the post-World War II period, US ICC economically regulated freight railroads experienced financial difficulties attributed to: (1) payment of property taxes on their rail rights of way (unlike US truck carriers that use public rights of way, i.e., government highways) and (2) costly railroad union work rules. The suppression of railroad intermodal and intramodal price competition from minimum-rate regulation made it difficult for railroads to lower their rates. In response, the US Congress passed the railroad economic deregulation acts—the Railroad Revitalization and Regulatory Reform Act of 1976 (commonly referred to as the 4-R Act of 1976) and the Staggers Rail Act of 1980.

Railroad Revitalization and Regulatory Reform Act (4-R Act)

Under the 4-R Act, railroad rates could be suspended by the ICC on the basis of being unreasonable. “Rates equal to or exceeding variable costs were not to be found unreasonable or unjust on the basis of being too low. A rate is no longer to be declared unreasonable on the basis of being too high unless the ICC first determines that a carrier has market dominance over the traffic involved. The ICC is required to develop market dominance standards” (Talley, 1983, p. 178).

The 4-R Act exempted US railroads from ICC economic regulation in the transportation of certain types of cargo, for example, fresh fruits and vegetables. US railroads responded to the growing list of cargo exemptions by reducing (increasing) rail prices when the freight transportation demand for exempt cargo was low (high) and the availability of rail equipment was high (low).

Staggers Rail Act of 1980

Although the 4-R Act reduced the ICC economic regulation of US railroads, the railroads continued to have financial problems. In response, the US Congress passed the Staggers Rail Act of 1980 to further reduce ICC economic regulation of US railroads, that is, “a railroad may establish any rate it desires so long as the rate contributes to going-concern value, a rate that equals or exceeds variable cost” (Talley, 1983, p. 178). The Act also established a revenue-to-variable-cost schedule for determining whether a railroad has market dominance over transportation service to which a challenged rate applies.

Economic Deregulation of US Truck Carriers

An investigation by the [Committee on the Judiciary of the US Senate \(1980\)](#) on the impact of US economic regulation of the US trucking industry found that economic regulation had negatively affected the industry by contributing to waste and inefficiency, absence of competition, and high rates in the industry. Under economic regulation, ICC truck carriers were restricted to hauling only those commodities so specified in their ICC certificates—thereby possibly resulting in trucks traveling without cargo (or traveling empty) on return trips.

In the early 1980s, there were “approximately 18,000 truck carriers under ICC regulation” and “generally only a few carriers served particular city-pairs. Hence, . . . far less competition among carriers in providing truck service than indicated by the size of the trucking industry” (Talley, 1983, p. 199). Under ICC regulation, truck-carrier rates were “based on value of service and not necessarily on the actual costs of providing the service, i.e., rates were set according to what the traffic will bear” (Talley, 1983, p. 199).

Motor Carrier Act of 1980

In July 1980, the US Congress passed the Motor Carrier Act of 1980 that provided for economic deregulation of the US trucking industry. The Act sought to promote a competitive and efficient trucking industry by “increasing opportunities for new carriers to get into the trucking business and for existing carriers to expand their services” (Talley, 1983, p. 200). With respect to pricing, the Act established a zone of rate freedom that permitted regulated truck carriers to raise or lower their rates by as much as 10% a year without ICC approval. Truck carriers were also permitted to carry deregulated and exempt commodities in the same vehicle at the same time.

Household Goods Transportation Act of 1980

Household-goods truck carriers transport personal effects of individuals as opposed to shipper-cargo truck carriers that transport shipper cargo. Since truck transport of household goods occurs relatively seldom in comparison to the truck transport of shipper cargo, the degree to which individuals understand the use of household-goods truck carriers in the transport of their personal effects is expected to be less than the degree to which shippers understand the use of shipper-good truck carriers in the transport of their cargo.

Given the unique nature of household-goods truck carriers, the US Congress's economic deregulation of household-goods truck carriers was considered separately from the economic deregulation of shipper-good truck carriers (as under the Motor Carrier Act of 1980) by passing the Household Goods Transportation Act of 1980 that sought to reduce unnecessary government regulation of household-goods truck carriers by establishing "new remedies and protections for their customers" (Talley, 1983, p. 201).

Nationalization

Nationalization "is the process of transforming private assets into public assets by bringing them under the public ownership of a national government or state" (https://en.wikipedia.org/wiki/Railway_nationalization). A nationalized freight transportation firm is owned by government versus an economically regulated freight transportation firm that is privately owned but economically regulated by government.

The objectives of a nationalized freight transportation firm in the provision of freight transportation service are those of the government owner, whereas the objectives of an economically regulated privately owned transportation firm in the provision of freight transportation service are those of the private owner of the firm subject to the economic regulations established for the firm by government. The management of a nationalized firm is less effective when its public managers pursue actions that are not in the interests of the government owners of the nationalized firm.

Nationalization of Railroads

Numerous countries have nationalized their privately owned railroads (Table 1). The United Kingdom and the United States nationalized privately owned railroads during World War I.

Privatization

Privatization is the transfer of the production (provision) of goods (services) from the public sector to the private sector. This transfer can occur from: (1) the sale of public assets to private owners to produce goods and provide services and (2) contracting-out of services formerly provided by the public sector to the private sector for provision.

The rationale for the privatization of goods formerly produced by government is to reduce the production costs of the goods. The rationale for privatization of services formerly provided by government is to reduce the provision costs of the services and to improve the quality of the services. The efficiency of privatization in the production (provision) of goods (services) increases when private managers of privatized firms find it in their interests to serve the public interest.

British Railways was nationalized in 1948 when placed under state ownership and its operations were placed under the control of the British Railways Board (BRB). British Railways was privatized in 1993, following passage of the Railways Act of 1993 (<https://en.wikipedia.org/wiki/Impact-of-the-privatisation-of-British-Rail>).

Table 1 Nationalization of railroads

Country	Year nationalized	Railroads nationalized
Argentina	1948	Argentine railways
Canada	1918	Canadian National Railway
France	1982	France's five main railways
India	1951	Indian Railways
Ireland	1953	Great Northern Railway
Japan	1906	Majority of Japan's private railway lines
Spain	1941	Broad-gauge railways
United Kingdom	1914	United Kingdom's railways (returned to their original owners in 1921)
United Kingdom	1948	The four major British railways—Great Western Railway; Southern Railway; London and North Eastern Railway; and London, Midland, and Scottish Railway
United States	1917	Following the entrance of the United States into World War I in 1917, President Wilson on December 26, 1917 nationalized most US railways under the Federal Possession and Control Act, creating the United States Railroad Administration (USRA) that took control of the railways on December 28, 1917. On March 1, 1920, following the end of the war, the railways were returned to their original owners.

Source: The information on the nationalization of railroads found in the table was taken from https://en.wikipedia.org/wiki/Railway_nationalization.

Under privatization, the operations of the BRB were broken up and sold and its various regulatory functions were transferred to the newly created office of the Rail Regulator. The ownership of infrastructure (including larger stations) was transferred to Railtrack, while track maintenance was to be provided by 13 companies across the network (<https://en.wikipedia.org/wiki/Railtrack>).

The ownership and operations of freight trains became the responsibility of two companies—English, Welsh & Scottish (EWS) and Freightliner. A significant change occurred in 2001 with the collapse of Railtrack and the passage of its assets to the state-owned Network Rail.

The Evolution of Freight Transport Policy

According to the definition by Slack et al. (2017), transport policy is related to the development of a set of propositions and constructs in order to achieve specific goals pertaining to economic, social, and environmental conditions jointly with the seamless and efficient functioning of the transport system. Transport policies have a paramount importance given that transport activities are at the core of virtually all social, political, and economic activities. Among the main factors influencing the development of freight transport policies in the last decades, it is important to underline the trend toward deregulation and privatization and the increases in world economic growth and in globalization. Both sets of factors have led to the rising importance of policies aimed at regulating, improving and making more efficient freight transport. Moreover, the 1980s and 1990s have witnessed the diffusion of multimodal transportation and of greater concentration on the supply sides of the markets for freight transportation (Reggiani et al., 2000). The move toward combined transport was caused by the concentration of transportation activities in ever larger firms that started to subsume transportation activities in integrated logistics chains. Another phenomenon that was at the base of this shift in freight transportation was the diffusion of third party logistics providers, which serve a large number of clients and take advantage of the emerging economies of scale and of scope in freight transportation. It must also be highlighted that some country policies (i.e., the Austrian system of ecopoints) constituted an important factor in the development of multimodal transportation.

In the last decade, the role of smartness in freight mobility policies has gained importance. This phenomenon has been clearly summarized in a report by Caltrans (2010), which has discussed the principles that should be at the base of smart transport initiatives. Among them, those related to freight transport mobility and policies are the following: (1) location efficiency; (2) reliable mobility; (3) robust economy; (4) health and safety; and (5) environmental stewardship. Location efficiency pertains to the integration of mobility and land use policies. Reliable mobility should be based on transportation network management and on multimodal mobility options. The robust economy principle should consider network performance optimization, the congestion effects on productivity, the efficient use of system resources, and the return on investment, with the aim of enhancing competitiveness. Health and safety should foster management and design practices that lessen exposure to pollution, minimize injuries and fatalities, and encourage active living. This principle is clearly linked to environmental stewardship, based on the reduction of the emission of greenhouse gases and of pollutants. The two latter principles lead to the issue of sustainability; a core topic of transport policies since the late 1990s.

One of the concepts that have been widely considered in order to minimize the impact of freight transport on the environment is the decoupling of transport growth from overall economic growth. A contribution by Schleicher-Tappeser and Hey (1998) has highlighted three basic strategies that may be pursued to accomplish decoupling: (1) the dematerialization of the economy via the replacement of material products with services, miniaturization and the increased durability of products; (2) a reduction of the spatial range of material flows by the use of incentives to increase local production for the local market; and (3) the optimization of transport organization. On the basis of a review of their review of the literature, Tight et al. (2004) proposed a slightly different taxonomy whereby the measures aiming at decoupling may be based on the moderation of demand growth, on modal shift, on increasing transport system efficiency and on improving vehicles and fuels.

On a more general sustainability level, a review paper by Ruamsook and Thomchick (2012) has proposed a conceptual framework of policies which partitions them into four categories:

- *Private sector operational strategies* are based on leveraging technology and implementing Information and Communication Technology (ICT) innovations in order to save fuel and reduce CO₂ emissions, on designing new packaging methods to minimize packaging size and to eliminate unnecessary packaging layers, and on collaborative (shipper-carrier, multishipper, and shipper-costumer) transportation to share capacity, to create round trips and to align delivery schedules.

- *Private sector strategic actions* include the restructuring of physical logistics systems, the training of personnel and compensation schemes and the alignment of incentives and performance measures. The first class of strategies concerns the location of warehousing and manufacturing sites in the proximity of large clusters of customers and/or supply facilities. Personnel training is aimed at optimizing the behavior of drivers in all phases of transport activities. The alignment of incentives and performance measure requires the involvement of all suppliers, carriers and third party logistics providers in changing and updating performance measures, altering contract specifications and modifying payment schemes. Moreover, performance metrics related to cost, quality, and time are required to take into account sustainability measures, such as reducing empty miles, freight comingling, the use of alternative fuels, route optimization and delivery efficiency and fuel reduction. Finally, differential price schemes should be implemented in case customers purchase a less than full shipment or less fuel-efficient transport modes.
- *Public sector operational actions* deal with the improvement of traffic capacity in the extant transport systems. Notable examples in this respect are represented by the application of intelligent transportation systems (leading to the reduction of emissions and congestion) and the restrictions on truck delivery hours in cities.
- *Public sector strategic actions* aim at changing substantially the transport systems and comprise incentives, facilitation, and direct regulation. The incentives can either take the form of pricing and taxation in the case of negative externalities (i.e., carbon pricing and cap and trade systems in the United States) or grants and subsidies if positive externalities are generated (i.e., the Diesel emission reduction act, the Air quality standard attainment program). The facilitation can be represented by grants for research and development (see, among others, Horizon 2020, which is the biggest European Union (EU) research program), as well as by new patents that constitute the instrument for sustainable transport options or by the pursuit of investments aimed at facilitating behavioral changes and modal shift in the operational, tactical, and strategic management of freight activities. Examples of possible regulations include emission and engine standards for all transport modes and the promotion of renewable fuel standards.

Freight Transport Policies in the European Union, United States and Asia

The previous section has highlighted the evolution of freight transport policies in the last decades and the general shift toward smartness and sustainability. The current section is devoted to the discussion of the main principles that have guided the freight transport policies that have been carried out in the EU, in the United States and in Asia.

European Union Freight Transport Policy

Before the beginning of the 1990s, freight transport policies in the EU were mainly based on local and national initiatives. Only the Single Act of 1986 and the consequent liberalization of the movement of goods (among other liberties) paved the way for unified EU freight transport policies. As a result, many of the interventions that were proposed in the 1990s aimed at establishing a common market. In this context, the strengthening of the Trans European Transport Networks constituted the main basis of the EU policies in this field. Moreover, many of the proposals carried out at the EU level were based on previous experiences in the EU countries. In 2011 the White Paper ([European Commission, 2011](#)) recommended a 20% reduction in transport emissions (excluding international maritime transport) between 2008 and 2030, and a reduction of at least 60% between 1990 and 2050. It also sought a 40% reduction in emissions from international maritime transport between 2005 and 2050. Consequently, as also indicated in the first section, a new emphasis was placed on sustainability issues and on the need to decouple economic growth from transport growth.

An interesting analysis carried out by [Aditjandra \(2018\)](#) by means of a literature review has highlighted that the EU freight transport policy has apparently been based on the following seven main pillars: (1) general freight issues, (2) rail, (3) port/maritime, (4) intermodal, (5) road freight and intelligent transport systems; (6) urban freight mobility, and (7) TransEuropean Networks (TENs).

With respect to general freight issues, the main themes that have emerged are transport planning, supply chain and green logistics. Rail freight concerns are mainly related to open access, material, and technology improvements and to modal shift initiatives. The port/maritime policy has targeted both the nodes in terms of port policies and the arcs with the possibility to establish the, so-called, motorways of the sea that were aimed at achieving the largest possible degree of modal shift from other (especially motorized) transport modes. The diffusion of intermodal transport was to be pursued mainly by the transfer of technology and terminal comodality. [Zografos et al. \(2012\)](#) proposed a taxonomy of the major policy impact areas:

- *Competition*—obtained through the improvement of market access rules, a reduction in the differences between transport related taxes, use based charging, a strategy for a common European maritime space, a freight oriented rail network, and a framework for fair competition among ports.
- *Efficiency*—based on the promotion of innovative technologies, the use of corridors in order to take advantage of the economies of scale, the training of freight personnel, the minimization of the infrastructure and technical limits to rail transport, and the diffusion of ITS and ICT systems.
- *Linkage of modes*—by fostering short sea shipping and the related land connections, simplifying the administrative burdens of freight transport chains, integrating waterborne transport modes, improving the quality of logistics services, and enlarging the capacities of ports and terminals

- *Social and environmental safety and security*—by the implementation of common security rules, the promotion of green transport and of energy efficiency in all modes, the introduction of new technologies and by facilitating cooperation among private and public stakeholders in different countries.

The main themes pertaining to road freight and ITS were related to the consideration of externalities and to the possible tax systems that may be put in place in order to internalize them. On the other hand, intelligent freight systems should be used to mitigate security risks, to improve the efficiency of freight transport activities and to coordinate road transport with other transport modes. At the local level, urban freight mobility should have the main aim to minimize the impact on air quality, to improve sustainability and to be based on proper planning in terms of land use in order to carefully implement an appropriate quantity of nodal infrastructure, such as warehouses and logistic platforms. In this context, the issues of value of time savings and reliability in freight transport, jointly with the related freight transport forecasts by means of innovative techniques and models, play a significant role in the strategic decisions of the policy makers (de Bok et al., 2018; de Jong, 2008). However, urban and regional freight transport policies should also be aimed at moving from traditional quantitative measurements of flows to qualitative considerations that would consider the economic impact at the local level and the enhancement of local industrialization and development processes (Zamparini, 2017). Moreover, efficient freight policies should manage to reconcile the heterogeneous interests of the various urban freight transport stakeholders (supply chain actors, resource supply actors, public authorities, residents, and visitors).

The main issues that have characterized the policies related to TENs for Transport (TEN-T) are the modeling of freight scenarios, the possibility to deploy green corridors and the regional impacts emerging from their implementation. The main aims of the TEN-T policy have been attained through the development of interoperability and of interconnectivity (Janic and Reggiani, 2001), in the light of the emerging era of globalization. Interconnectivity requires the coordination of various transport modes to deliver door-to-door services, while interoperability deals with the possibility to use compatible and standardized equipment, technology, facilities, and infrastructure with compatible vehicles.

It should also be noted that the 2030 Agenda for Sustainable Development, adopted by all United Nations Member States in 2015, will certainly move current freight transport policies toward more innovative solutions, with the aim of fulfilling the 17 Sustainability Goals. Concerning the EU, the related EU documents approved in 2016 and 2017 (European Commission, 2019) show the EU initiatives within this framework, such as the multistakeholder platform on SDGs, set up on May 22, 2017, which aims to provide a forum for the exchange of experience and best practice on the implementation of the SDGs across sectors and at local, regional, national and EU level. The efforts of the EU toward achieving an integrated sustainable policy at all spatial levels (EU, national, regional, urban and local) should be emphasized in this respect.

United States Freight Transport Policy

A document published in 1997 by the Department of Transportation (DoT, 1997) has set the eight main principles that should guide the United States freight transport policy.

- The first principle was related to the provision of funding and of a planning framework that would establish priorities for the allocation of Federal resources to cost-effective infrastructure investments to support broad national goals. In this respect, the Federal administration would intervene either to facilitate the resolution of a freight transportation problem or to fund projects with a national significance. Under the same principle, rigorous cost benefit analyses were deemed necessary for all proposed investment initiatives.
- The second principle aimed at promoting economic growth by removing unwise or unnecessary regulation and through the efficient pricing of publicly financed transportation infrastructure.
- The third principle stated the necessity to ensure a safe transportation system. This would require both public regulation and enforcement and private voluntary compliance efforts that should be supported.
- The fourth principle endorsed the protection of the environment and the conservation of energy. The cooperation of all levels of government and the private sector was considered an important requirement to fulfill this goal. In this respect, the federal government was called to reduce the social costs of transportation and to devise taxes and subsidies that would consider the negative and positive externalities generated by transportation activities. Research and technology development were considered as the two most important drivers of the minimization of environmental impact and energy conservation.
- Coherently, the fifth principle advocated the use of advances in transportation technology to promote efficiency, safety, and speed.
- The sixth principle aimed at fostering policies that would effectively meet defense and emergency transportation requirements. The main focus of this principle in 1997 was related to facilitating an efficient response to natural disasters. It is evident that, after the events of September 11 2001, the focus drastically shifted toward the enhancement of security against terrorist acts, with a clear reorganization of the responsible Federal agencies.
- The seventh principle aimed at facilitating international trade and commerce by upgrading the existing facilities that connected the country to global supply chain systems.
- The last principle fostered the promotion of effective and equitable joint use of transportation infrastructure for freight and for passenger services, with a particular emphasis on the consideration and minimization of the safety issues that may arise from this conjoint use.

Table 1 Policies on the infrastructure systems that impact on freight transport

	<i>Federal</i>	<i>State</i>

Source: Authors' elaboration based on *NASEM (2011)*.

A report by the National Academies of Sciences, Engineering, and Medicine (*NASEM, 2011*) has clarified that the Federal administration has deployed in the last decades two major roles: funding and regulation. The report also provides a taxonomy of the policy categories that may affect the various modes of freight transport and constitutes, therefore, an update of the report issued in 1997 (*DoT, 1997*): (1) safety, (2) security, (3) land use, (4) environment, (5) energy and climate change, (6) trade and economic regulation, (7) infrastructure operations and management, (8) infrastructure investment, and (9) infrastructure finance.

Safety policies that have been implemented at the federal level include truck, railroad, and aviation hours-of-service rules, interstate speed limits, truck speed governor rules, truck electronic onboard recorder rules, rules for the inspection of truck and vehicles, rules for aircraft design, hazmat rules, and Coast Guard rules for barges and barge operations. At the state level, highway speed limits, the enforcement of federal truck rules and restrictions on locomotive horns. Federal security policies are the transportation worker identification credential, truck driver background checks, US exit fingertips rules, maritime administration foreign crew ID requirements, airport security protocols, chemical facility antiterrorism standards, and screening of cargo on passenger aircraft and of import containers, customs rules, and programs. At the state level, it is worthwhile mentioning routing and infrastructure access restrictions. Federal and state land use policies affecting freight transport are respectively represented by brownfield programs and by land use planning requirements. Federal environmental policies are constituted through emission and fuel standards, air quality standards and planning requirements, the management of dredging spoils, water pollutant discharge rules for vessels, and oil spill prevention rules. With respect to energy and climate change policies, it is possible to highlight at the federal level the requirements or subsidies for renewable fuels, the greenhouse gases emissions regulations and the programs and financing to improve fuel efficiency and to introduce alternative fuels. Most of these policies are also pursued at the state level.

Table 1 provides a list of examples of policies related to the infrastructure system that have an impact on freight transport.

Asian Freight Transport Policies

A report by the Asian Infrastructure Investment Bank (*AIIB, 2018*) provides a clear picture of the situation of the transport system in Asia and of the related needs in terms of policies and investments. Despite the importance of transport for trade and economic development, the provision of transport infrastructure and services is highly uneven across Asia and, for most countries, it lags behind that of developed economies. Policies aimed at upgrading and making more efficient the provision of transport infrastructure and systems are particularly important in a region that is generally marked by rising degrees of affluence and freight transport demand. Consequently, freight transport policies should provide the necessary connectivity among countries. At the time of writing, there are five main initiatives in this respect:

- The ASEAN connectivity initiative focuses on sustainable infrastructure and seamless logistics within ASEAN countries.
- The Central Asia Regional Economic Cooperation program defines six transport corridors among the 11 countries participating in the initiative with a particular emphasis on rail, roads, and dry ports.
- The Greater Mekong Subregion Cooperation program involves Cambodia, China, Lao People's Democratic Republic, Myanmar, Thailand and Vietnam, with the aim of facilitating crossborder freight transport with a mixture of infrastructure and of immaterial investments.
- The South Asia Subregional Economic Cooperation program aims at promoting crossborder transport networks and the reduction of freight transport costs among Bangladesh, Bhutan, India, Maldives, Myanmar, Nepal and Sri Lanka.
- Last, the "One Belt, One Road" initiative or "Belt and Road Initiative" is mainly backed by the Chinese government and is not just related to transportation. It involves Asian, African and European countries and its stated purpose is to increase economic cooperation and prosperity among countries. In this context, freight transport is expected to play a very important role. The

expected outcomes are a rebalancing of modal shift with a lower dependency on road transport, a higher diffusion of multimodal transportation chains, an enhanced rail–road connectivity in Central Asian Countries and the development of several logistics hubs in Eastern Europe, Central Asia, and the Middle East.

As for India, a report by the [National Transport Development Policy Committee \(2014\)](#) has stated that the main objective of Indian freight transport policies lies with the creation of an interconnected, hierarchical, and integrated transport network. In this context, a rebalancing of modal shift toward railway transport is considered as an important achievement, both in terms of sustainability and energy efficiency. Moreover, the creation and completion of a series of dedicated freight transport corridors is envisaged jointly with the provision of new local ports for the diffusion of coastal shipping, dedicated facilities for air cargo in airports and various logistics parks close to the main metropolitan areas. In terms of governance, the proposals re aimed at creating a stable Transport Ministry and an Office of Transportation Strategy, at providing a comprehensive regulatory environment and at decentralizing policy decisions, where appropriate, to urban and metropolitan governments. Urban freight management is likely to become a pressing issue in all cities in Asia (and in the rest of the world). Appropriate policies should reduce the need to move goods, to shift local freight transport to more sustainable modes and to improve the operations, technologies, and energy efficiency of current road freight transport ([GIZ, 2013](#)).

Conclusions

This review of freight transport policies has underlined the fact that, in this current era of increasing connectivity, networking, and globalization, the urgent objective of achieving sustainable transport, as established by the SD-2030 Agenda, will most probably raise the issue of how to develop current freight transport policies in the EU, the United States and Asian Countries toward common policy strategies at a very global level.

Introduction

Logistics encompasses a diversity of activities concerned with the management and the operation of goods flows, including transportation, handling and packing, warehousing, transshipment, pre- and post-manufacturing, and supply chain management. Within this large economic sector, three main logistics functions can be identified: international flows, regional distribution, and city logistics. The management of international flows is a crucial task in a context of global production and distribution networks (Coe, 2014). International flows mostly rely on maritime and air transport modes—key infrastructures are thus seaports and airports. However, most goods flows are national or regional and are managed by regional distribution systems. They depend on, mainly, road and, secondary, rail and river transport modes. Warehouses, often called distribution centers (DCs) (section, Logistics Zones: The Silent Privatization of Ordinary Logistics Spaces), represent crucial nodes to (re)organize shipments within regional distribution systems (Hesse, 2008). Intermodal terminals can be needed for transshipments from the different transport modes. Eventually, city logistics, also called last mile logistics, corresponds to the final step of the delivery process. It is mainly performed by light trucks even if greener vehicles (electric vans and cargo cycles) are now being experimented with. These logistics services can need specific facilities in dense parts of metropolitan areas (Browne et al., 2019). Most logistics flows articulate these three functions, which are required to connect the production of goods to their consumption and their recycling. Thus a large range of logistics spaces—seaports, intermodal terminals, logistics parks, DCs, urban consolidation centers to name a few—have been built during the last decades in order to perform these different logistics activities.

The diversity of logistics spaces, however, does not only reflect this diversity of logistics functions. In this perspective, the way these spaces are planned, produced, regulated, governed, financed, maintained, and accepted by local communities matters a great deal. In other words, logistics spaces display different configurations corresponding to their institutional, political, economic, and social environments (Hall and Hesse, 2013).

This chapter proposes an exploration of the way current logistics spaces are planned and financed by the different public and private actors involved. It will highlight the impacts of planning policies and financial circuits on their spatial and institutional configurations. In this perspective, along with their logistics roles, the chapter underlines three main dimensions of the current systems of production of logistics spaces: the modalities of the financialization of logistics properties, the scope and effectiveness of planning policies for logistics facilities, and the scope of traditional public infrastructure regulations and management regimes. These three main dimensions are indeed the three central variables of the existing modes of governance of logistics spaces.

The outline of this paper is as follows. The next section is dedicated to logistics zones, where most warehouses and distributions centers are concentrated. Current logistics zones are embedded in historical industrial urban areas or correspond to new private business parks. In the second next section, the specific mode of governance of international gateways (airports, seaports, and inland ports) is analyzed as a part of traditional public infrastructure policies. Against these two main configurations of logistics spaces production, the role of current spatial planning policies for logistics facilities are investigated in the third next section.

Logistics Zones: The Silent Privatization of Ordinary Logistics Spaces

The development of logistics activities and flows entails the construction of thousands of warehouses and DCs that are mainly concentrated in logistics zones in urban regions. This section presents a typology of three kinds of logistics zones based on the comparison of different European and North American case studies in the urban regions of Paris, Atlanta, and Frankfurt (Raimbault et al., 2019; Barbier et al., 2019). This typology indicates the existence of different modes of logistics zone governance, corresponding to different phases of logistics development, planning, and financing regimes. A comparison with case studies in other regions could reveal the existence of other modes of logistics zone governance.

Warehouses, Distribution Centers, and Logistics Zones

Warehouses and DCs are industrial sites dedicated to logistics operations. Shippers and logistics providers both operate warehouses and DCs within their distribution networks. In these sites, four basic operations are performed: the pickup of goods, consolidation/deconsolidation of shipments, change from one means of transportation to another, and storage. In contrast to traditional warehouses, DCs are designed in order to minimize the storage of goods and to keep goods as mobile as possible in a context of just-in-time flows (Cidell, 2015): the goods are collected from different origins, grouped in DCs, and then redistributed to their respective destinations. DCs are the contemporary configuration of warehousing.

Yet the establishment of DCs is not solely the result of corporate logistics strategies. These buildings of thousands of square meters are subject to several spatial planning regulations, as well as land development and real estate investment strategies. In most developed countries, municipalities and local communities design and implement local zoning plans that authorize the use of land for establishing DCs. They also issue the required building permits. Through this process, the real estate industry (land developers, developers and investors) come under the influence of local public and even political power that is expressed in planning regulations or social movements. Moreover, some local governments initiate the development of new business zones dedicated to logistics facilities.

The development of logistics activities during the last decades has led to the emergence of different kinds of business zones concentrating logistics facilities. Some logistics zones are former industrial zones, while others are planned by local government or produced by property investors.

From Industrial Zones to Logistics Zones

During a first period of logistics development (1970s–1990s), logistics providers and shippers, looking for sites in urban regions to build warehouses, found spaces in the large existing industrial zones of European and North American cities. Warehouses have replaced former factories or have been built on plots that became available, when the demand for new manufacturing sites declined. This process has led to the incremental conversion of industrial zones into logistics zones.

The establishment of these logistics sites is not based on complex political negotiations, or specific real estate or land development operations. The land, generally developed by public land developers, is available for any type of industrial purpose, whether manufacturing or logistics. Municipal authorities are only asked to give their formal agreement by signing the building permits. The shift to logistics of these former industrial sites is therefore almost invisible, without explicit public discussion or negotiation between public and private stakeholders.

The silent conversion of industrial zones into logistics zones corresponds in this way to a first mode of governance of logistics zones, which is limited to the enforcement of generic rules of land use, and does not tilt local political agendas toward other issues of logistics industry development. It mainly takes place in the former manufacturing belt in metropolitan areas (Raimbault et al., 2019).

Local Policies of Logistics Zones Development

The increasing demand for logistics spaces has led to a second generation of logistics zones corresponding to another mode of governance. Many local governments or authorities implement economic development policies based on attracting logistics facilities in order to increase their tax revenues and the number of local jobs. The implementation of this agenda consists of publicly developing new business zones dedicated to logistics activities.

Thus local governments plan new logistics zones in their territory and invest in the corresponding land development operations and in the subsequent road (and sometimes rail or river) infrastructure. Then they sell the plots directly to shippers or logistics providers looking for new logistics sites or, much more often, to property developers building DCs in order to rent them. Some municipalities also plan and finance rail or river container terminals in these zones, in order to strengthen its attractiveness or to favor more ecological transport modes.

In this way, the development of this second generation of logistics zones is the result of voluntarist local spatial planning policies. This mode of logistics zone governance focuses on land development issues, at the expense of other issues such as employment or housing and public transport for the workers of the zone. Moreover these logistics zones are only planned at the municipal scale (Cidell, 2011). In most urban regions, the issue of planning logistics zones is not in the scope of regional or metropolitan planning policies (section, Planning Policies for Logistics Facilities: Between Regional Planning and Local Urban Logistics Innovations). Thus,

in the absence of strong planning policies at this scale, these local policies result in logistics zones spreading toward suburban and outer-suburban areas, participating in the process of “logistics sprawl” (Dablanc and Ross, 2012). However, the development of suburban zones can meet with objections from environmentalists, which can hinder the sprawl (Barbier et al., 2019).

Financialization of Logistics Real Estate and Emergence of Private Logistics Parks

Since the 1990s, logistics firms have largely opted for flexible real estate solutions and thus have looked for warehouses to rent, rather than building and managing their own facilities. This has contributed to the emergence of a development and investment market in logistics real estate (Hesse, 2008), which refers to the general process of the financialization of real estate. The financialization of logistics real estate is connected to a third mode of governance that is specific to the private logistics parks.

The logistics real estate market is dominated by international firms, which specialize in logistics and manage global investment funds. These companies take direct charge of the development of the warehouses they buy, as investment fund managers. In order to reduce their dependence on negotiations with local public authorities, they also tend to be the developers of the logistics zones in which they invest. In other words, instead of building warehouses scattered around different business zones, the industry leaders develop private logistics zones containing several warehouses. These “logistics parks” are entirely owned and operated by the same investment fund manager responsible for property management. They are fenced and protected by private security.

This business model leads to the privatization of a number of local policies. Logistics real estate firms privatize land development policies, compared to the situation of business zones directly developed by local governments. To the extent that logistics parks are entirely private, real estate firms become the *de facto* owners and managers of the streets and green spaces that constitute the public spaces in the business parks. Moreover the model also enables real estate companies to decide on local economic development issues, insofar as they select the firms that settle in the municipality, which considerably affects the latter’s economic specialization and prospects.

However, logistics parks must be authorized and supported by local governments, which are responsible for issuing spatial planning documents and building permits. The production of logistics parks implies that the local authorities accept this dynamic of privatization. Different mechanisms explain this political choice. First, some local authorities in the outer suburbs lack the financial, technical and even political resources needed for developing business zones. In order to get the capacity to attract logistics sites in their territory, they look for private investors able to establish private business zones. Second, some outer suburban municipalities argue that the private logistics park model is superior to traditional publicly developed business zones: the general design of the park and the fact that it is fenced and secure, the fact that private development and management of parks makes no demands on the public purse, eventually the fact that the property manager is solely responsible for the entire park and can be contacted directly by local governments. These different aspects of private logistics parks give local governments a greater sense of control over their territory.

This last mode of governance, dominated by the logistics real estate industry, becomes dominant in large urban regions prone to strong political fragmentations. The consequences are twofold. At the local scale, local governments negotiate only with property developers and investors. They rarely meet the users of the warehouses, the workers, or even the logistics firms themselves. Managing the relations with the firms that rent the warehouses becomes the task of the property manager alone. In consequence, logistics issues are seen as a question of real estate, disconnected from matters relating to logistics activities and employment, such as employee transport or transfer of goods flows from road to rail or river modes. At the regional scale, private logistics parks directly challenge planning policies (section, Planning Policies for Logistics Facilities: Between Regional Planning and Local Urban Logistics Innovations). As these real estate products are particularly attractive for outer-suburban areas, where local authorities do not have the resources or the desire to develop logistics zones alone, the financialization of logistics real estate largely contributes to logistics sprawl.

The evolution of the planning and financing regimes dedicated to logistics zones, from traditional industrial zones to private logistics parks, is due to the emergence of a global financialized development and investment logistics real estate market. In a double context of weakness of planning policies for logistics facilities at the metropolitan scale and of the lack of financial, technical and even political resources in many local authorities in the outer suburbs, the financialization of logistics real estate leads to the privatization of the production of logistics spaces in many metropolitan areas. Besides this fragmented mode of governance of logistics zones, the management of international gateways (airports, seaports, and inland ports) corresponds to a specific mode of governance tied to traditional public infrastructure policies.

International Gateways: Planning and Financing Public Logistics Infrastructures

Maritime transportation represents between 70% and 80% of the total of international flows, with the rest mainly completed by air transport (Rodrigue et al., 2017). Efficient transshipment facilities from maritime and air transport to land transport modes are thus needed for international flows. Airports, seaports and also different kinds of inland ports, that complement maritime gateways, constitute the systems of international gateways. As they are framed as being of strategic importance by local and national governments, international gateways are mainly organized and managed by public or semipublic authorities, which constitutes specific modes of governance of logistics spaces. Most airports and seaports and some inland ports thus constitute emblematic cases of logistics spaces planned and financed as public infrastructure.

The Logistics Facilities of International Gateways

International gateways are based on two main kinds of facilities. First of all, intermodal terminals are used for the transshipment of goods from maritime or air transport to land transport modes. Seaports are organized around container terminals and different types of bulk terminals (dry and liquid bulk, general cargo, and roll on/roll off). These terminals are usually operated by private terminal operators, which can be subsidiaries of the main maritime shipping companies. In airports, cargo stations organize the links between airport runways and trucking. These facilities are directly rented by air, courier, and express delivery companies.

Airports and seaports also concentrate numerous other logistics facilities needed for the organization of hinterland flows. On the one hand, shippers' DCs and carriers' parcel service facilities are located in the domain of seaports and airports in order to organize the different inland shipments at the local, regional, national, and continental scales. On the other hand, some river and rail (containers and bulk) terminals are usually localized in seaports, as rail and river transport modes can be efficient hinterland transport solutions.

Several inland ports complement the major seaports. Inland ports are "inland facilities with or without an intermodal terminal and logistics companies, which [are] directly connected to seaport(s) with high capacity transport mean(s) either via rail, road or inland waterways, where customers can leave/pick up their standardized units as if directly to a seaport" (Witte et al., 2019, 54). They offer the services of an extended gateway within the context of seaports becoming integral parts of extensive hinterland networks, intermodal transport corridors and inland ports (Notteboom and Rodrigue, 2005). Inland ports are located in different cities of different size, from small cities located on major transport corridors to large urban regions.

International gateways are thus complex logistics spaces, corresponding to different scales of flows, different modes of transport, and different logistics services. A large variety of logistics firms are involved in international gateways, which supposes specific institutional arrangements in terms of infrastructure, land and operations management.

International Gateways Governance: The Production of Logistics Spaces and Services

The way most seaport spaces are produced and governed is emblematic of the specific public infrastructure mode of governance. Even if there is a diversity of governance configurations, the governance of airports and inland ports generally corresponds to this infrastructure mode of governance (Rodrigue et al., 2010).

The ownership, management, and operation of the facilities of seaports and airports are rarely entirely public or entirely private. Concerning seaports, the most common configuration is known as *Landlord port* (Brooks and Pallis, 2012; World Bank, 2007). This mode of governance is based on the separation of public and private spheres of intervention. A public port authority (PA) is responsible for the production and the maintenance of the port spaces, while the private operators are responsible for the production of the different logistics services and the private facilities needed for them. In some seaports, especially in England (Baird, 2006), the ownership, the regulation and the operation can be the responsibility of the private sector. This mode of governance, known as *Private Service port*, remains much less common than the Landlord port. The ownership of airports is often public, while the management of the infrastructure can be entrusted to a private operator under a concession contract. Some inland ports are governed by PAs according to the principle of a Landlord port. The next sections develop the way logistics spaces are planned and financed in the case of a Landlord port. This configuration corresponds to the most common mode of governance for international gateways.

PAs are organized as public corporations that are accountable to a local (municipal or regional) government (for instance: the case of Antwerp in Belgium or Los-Angeles and Long Beach in United States) or a national government (the case of Marseille and Le Havre in France). They produce and maintain port spaces with an overarching goal of financial self-sustainability. Besides public subsidies, most of their revenues come from port dues and land leases. Thus, PAs aim to increase port traffic, in order to collect port dues, which requires financing and providing plots for efficient terminals, and land uses, in order to increase their land revenues, which requires financing and providing attractive plots to rent for industrial sites.

In a Landlord port, the PA owns the land and the collective infrastructure (docks, roads, railways and waterways). It manages nautical issues, land use planning and the promotion of the port in general. The role of the PA is thus mainly focused on the production of different kinds of port spaces. It finances, produces and maintains the infrastructures mentioned above. Moreover, it acts as a public land developer in order to attract two kinds of companies in the port domain. On the one hand, it produces terminal land (docks, wharfs and quay walls). Private terminal operators rent the land through long-term administrative leases and finance the construction of the terminals they operate. On the other hand, in the rest of the port domain, it also produces the land plots that enable logistics or manufacturing firms to establish industrial sites in the port domain. These firms contract administrative leases for the lots where they construct and own their DCs, parcel service facilities or factories. In the context of the financialization of logistics real estate, numerous property investors lease land in seaport domains in order to build DCs to rent. In this way, even with the growing importance of property investors, the land remains under public ownership and control.

The planning of the different facilities and plots are negotiated with local or national governments according to the local and national institutional configurations. The autonomy and the financial responsibility of PAs are important in this domain. Besides, the major strategic projects, such as port extensions or the construction of new transport ways toward the port (railways, waterways or highways) are planned and financed with local or national governments that exert control over PAs, in the framework of transport infrastructure planning policies.

PAs are not only concerned, therefore, with the production of spaces, but also with the flows and logistics services issues. The negotiations on the leases are a tool enabling port authorities to choose companies that will generate traffic or, from a sustainability perspective, greener practices (e.g. river and rail traffic instead of road traffic, slow steaming). PAs usually develop strong relationships with the companies established in the port domain. They can then provide advice and sell business research services. With the companies forming port communities, PAs act as managers of “port clusters”, which are characterized by “various forms of coordination and resource sharing as a consequence” of the cluster of firms in the port (de Langen and Haezendonck, 2012, 638).

The management of international gateways corresponds in this way to a specific mode of governance tied to public infrastructure policies. The public control on the production of logistics spaces and the involvement of PAs in flows and logistics services issues clearly contrast with the privatized production of logistics parks and the indifference of local governments over logistics issues. These two parallel modes of governance of the logistics spaces are thus often at work in cities and regions. The next section analyses the potential articulation of these two modes of governance within emerging planning policies for logistics facilities at the scale of metropolitan areas and regions.

Planning Policies for Logistics Facilities: Between Regional Planning and Local Urban Logistics Innovations

Logistics is now included in most regional and metropolitan agendas, framed mainly as an issue of sustainability. It leads to spatial planning policies for planning facilities and to policies favoring greener city logistics practices.

Regional and Metropolitan Spatial Planning Policies

Regional and metropolitan spatial planning policies have increasingly included logistics spaces issues, often framed as an issue of sustainability. For instance, in the Paris region, regional planning documents aim to limit the logistics sprawl in order to reduce the urbanization of new spaces. The logistics sprawl is also framed as being at odds with the goal of modal shift of freight flows from road to river and rail modes (Raimbault et al., 2019). However, as developed in section (Logistics Zones: The Silent Privatization of Ordinary Logistics Spaces), the governance of logistics zones development remain essentially local in most urban regions. Indeed, despite these ambitions, regional or metropolitan planning policies are rarely legally binding for municipal land use plans. Comparison between US metropolitan areas, the Paris region and the Frankfurt metropolitan area shows that, Paris region planning policies include logistics issues more clearly than in the US metropolitan areas (Raimbault et al., 2019) and that land-use legal restrictions are weaker in the Paris region than in the Frankfurt case. As a consequence, Frankfurt’s planning regulations restrict the space available for logistics, reduce logistics sprawl and the development of huge private logistics parks compared to the Paris region and US metropolitan areas (Barbier et al., 2019).

In this context, seaports, airports and inland ports can be considered as public tools for implementing logistics regional planning. Against the fragmented governance of logistics zones, a planning solution consists of working with the already existing public authorities dealing with logistics spaces such as (air)port authorities. This situation explains the role of river port spaces and institutions in the regional planning policies of the Paris region (Raimbault, 2019). Indeed, the Paris regional master plan aims to concentrate the development of logistics sites around the main rail and river terminals, which corresponds to spaces managed by the river PA. In this way, the public infrastructure mode of governance meets some goals of the regional planning policies.

Eventually, spatial planning policies also aim to preserve spaces for urban logistics sites in dense urban areas close to city-centres.

Local Urban Logistics Innovations

Besides spatial planning, in order to limit “logistics sprawl,” and thus to comply with sustainability goals, some municipalities facilitate the supply of logistics facilities in inner areas. The literature provides several examples, mostly in Paris and Tokyo (Diziain et al., 2012; Raimbault et al., 2019; Dablanc, 2019), of policies developing new formats of urban warehouses in city centers and dense urban places.

In this domain, flagship projects consist of multistory urban buildings, where logistics activities (consolidation centers, rail terminals, small storage facilities) coexist with several types of activities such as housing, offices, sport, and leisure facilities or even datacenters. The purpose of cohabitation is that these activities bear a portion of the cost of building and land, since they are more profitable. This financial equalization strategy would allow logistics to return to dense urban areas at an acceptable cost.

While private real estate investors are involved in the development of suburban logistics zones, they are just emerging in the development of dense urban logistics buildings. The latter are generally developed by public stakeholders backed by municipalities, as the profitability of such real estate operations is still hazardous. The support of public authorities is crucial in these projects, which can slow down the diffusion of this type of logistics format, as it can make investors risk averse. Urban logistics infrastructure has, to this day, relied mostly on the public initiatives of municipalities, which indicates a third mode of governance of logistics spaces.

Conclusions

The chapter underlines three main dimensions of the current systems of production of logistics spaces: the modalities of the financialization of logistics properties, the scope and effectiveness of planning policies for logistics facilities, and the scope of traditional public infrastructure regulations and management regimes. The different combinations between these three main dimensions explain the coexistence of different modes of planning and financing logistics zones, international gateways, and urban logistics infrastructure.

At the metropolitan scale, the result is a “dualization” of the governance of logistics spaces (Heitz, 2019). On the one hand, international gateways and urban logistics facilities are governed thanks to specific public planning and financial tools. On the other hand, suburban logistics zones are prone to strong privatization dynamics and largely remain out of the scope of regional planning policies and regulations.

These conclusions indicate two main research perspectives. First, the analysis of the coexistence of different modes of governance should be developed through new systemic approaches to the coevolution of the different spaces and modes of governance of logistics dynamics, for instance at the scale of urban regions (Raimbault, 2019). Second, as this chapter is mainly built on European and North American case studies, these findings should be challenged by future international comparisons with Asian, Latin American, Middle Eastern, and African case studies.

Biography

Nicolas Raimbault is an Assistant Professor at the University of Nantes, researcher at ESO (Espaces et Sociétés, UMR CNRS 6590, France) and research fellow at Luxembourg Institute of Socio-Economic Research (LISER, Luxembourg). He teaches urban geography, urban planning, and urban policies and his research deals with the urban and social impacts of logistics activities development. His current work investigates the transformations of blue-collar places and their governance in the dual context of the rise of logistics blue-collar jobs and the fall of manufacturing jobs in European and North American urban regions. He completed his PhD in urban studies in 2014 at Paris-Est University. His PhD thesis studies the governance of logistics development in the Greater Paris Region and in the inland corridor of the port of Rotterdam in the Netherlands. He also received a Master's degree in regional and urban affairs from Sciences-Po Paris.

Introduction

Supply chains involve supply chain risk: every supply chain professional knows that. And as global cross-border trade continues to increase, and supply chains lengthen, that risk mounts. Observers point regularly to the threats posed by currency fluctuations, supplier failures, geopolitical uncertainty, infrastructure failings and natural disasters. Time and again, events demonstrate how diverse those risks can be—and how interconnected are the world's factories and supply chains.

Consider the earthquake and ensuing tsunami, which hit North-eastern region of Japan in 2011. Within a matter of hours, large parts of Japan's automotive industry had ground to a halt. Honda, Toyota, Nissan, and Subaru all had plants in or close to the affected zone, and were forced to close them. And soon, other Japanese automotive plants—in many cases far less directly affected by either the earthquake or the tsunami—were also forced to stop production, because of parts shortages caused by postdisaster logistics difficulties, or by earthquake or tsunami damage to tier-1, tier-2, or tier-3 suppliers' plants.

Toyota, Suzuki, and Nissan ceased production completely. Even Mazda, located far to the south near Hiroshima, closed down—unable to keep its plants running without critical parts sourced from suppliers closer to the damage zone. Take into account the 10 days of unaffected production prior to March 11, when the earthquake struck, and postearthquake volumes for the rest of March were close to zero.

Inevitably, the disruption soon spread offshore, affecting manufacturers as diverse as Ford, Volvo, GM, Renault, Chrysler, and PSA Peugeot–Citroën. Across Asia, North America and Europe, crippled assembly plants either shut, or scrambled to build whatever vehicles they could, with the components, materials, and paint colors that were available.

Simply put, the world's automotive industry found that huge numbers of components turned out to be sourced from Japan and its intricate supply chains. What made matters worse was that in many cases, many of these components were single-sourced—and single-sourced not just to a single company, but to a single manufacturing plant within that company. A widely used metallic paint pigment, called Xirallic, had been produced at only one factory in the world, located in a town close to Fukushima.

It might be thought easy to dismiss this supply chain disruption as a “one off;” an unfortunate outcome from a natural disaster that is extreme by any standard. Except, of course, for the fact that a little thought reveals plenty more examples from the last few years.

The 2010 eruption of Iceland's Eyjafjallajökull volcano, for instance, filled European air space with high-altitude ash clouds, and led to the closure of much of Europe's air space, and resulted in the cancellation of some 95,000 flights, causing significant disruption to air freight schedules. Again, the automotive industry's lean supply chains were quickly affected, with production halted at two Ford plants in Michigan as well as at BMW's plant at Spartanburg, South Carolina.

Or the flooding in Thailand in October 2011, which submerged seven of the country's largest industrial zones, causing national manufacturing output to fall by 36%. In the country's Khlong Luang industrial zone, factory floors lay under up to 2 m of polluted water for several weeks and, of the 227 factories operating in the zone, a mere 15% had restarted production six months later. Two of the world's largest manufacturers of computer hard drives—Seagate and Western Digital—had factories in Thailand, with Western Digital reporting that it manufactured 60% of its hard drives in the country.

In short, in each case, events on the other side of the world had supply chain impacts on businesses and end-consumers thousands of miles away. Contingency plans had been of little use, the events in question could not have been predicted, and in many cases the affected businesses did not know the extent of their vulnerability until it was too late.

What can businesses do to improve their resilience to such supply chain disruption? How can they reduce their risk profile? What changes do they need to make to their organizations, and their supply chains? This chapter explores the answers to these questions.

Figure 1 The drivers of supply chain risk.

Categorizing Supply Chain Risk

It is possible to think of supply chain vulnerability to risks as being split between external and internal “drivers,” as shown in **Fig. 1**. Importantly, risks will always be context-specific and because every supply chain is different, then risks and their relative weightings will always be different.

External risks can be summarized as follows:

- **Demand risk**, which relates to potential or actual disturbances to the flow of products, information and cash, between the focal firm and its market. Cash resources are rarely considered, but in economic downturns can prove to have significant impact on the operating capability of organizations.
- **Supply risk** is the upstream equivalent of demand risk; it relates to potential or actual disturbances to the flow of product or information upstream of the focal firm. In a similar way to demand risk, the disruption of key resources coming into the organization can have a significant impact on the organization’s ability to perform.
- **Environmental risk** is the risk associated with external and, from the firm’s perspective, uncontrollable events. The risks can impact the firm directly or through its suppliers and customers. Environmental risk is broader than just natural events like earthquakes or storms. It also includes, for example, regulatory changes such as alterations to legislation or customs procedures.

Internal risks relate to both how the firm addresses the external risks that it faces, and its competence in planning and executing its own business:

- **Processes** are the sequences of value-adding and managerial activities undertaken by the firm. Process risk relates to disruptions to key business processes that enable the organization to operate. Some processes are key to maintaining the organization’s competitive advantage, while others may underpin the organization’s activities. It is important to recognize and classify the importance of the various processes to enable effective risk management strategies to be implemented.
- **Controls** are the assumptions, rules, systems, and procedures that govern how an organization exerts control over the processes and resources. In terms of the supply chain these can include such things as order quantities, batch sizes, and safety stock policies, plus the policies and procedures that govern asset and transportation management. Control risk is therefore the risk arising from the application or misapplication of these rules.
- **Mitigation** is a hedge against risk built into the operations themselves and, therefore, a lack of mitigation is a risk in itself. It is important to consider mitigation during the supply chain design process, as if this is not done, then the risk profile can be increased. Allied to mitigation is the notion of *contingency*, which is the existence of a prepared plan for dealing with risk, and the identification of resources that can be mobilized in the event of a risk materializing. This requires every stakeholder in the supply chain to understand which resources should be mobilized, and the correct procedures for doing this.

Constructing Resilient Supply Chains

When building a resilient supply chain, four key things need to be considered:

- The supply chain design
- How supply chain agility can be engendered

- How collaborative supply chain relationships can be established
- How a culture of supply chain risk reduction can be fostered

Let us now address each of these areas in turn.

Supply Chain Design

Fairly obviously, supply chains do not operate in a vacuum. In particular, when considering the design of the supply chain, it is important to maintain a clear linkage to the corporate and competitive strategies of the business. In other words, if the overarching strategy of the business is to compete on, say, price, or service, or the ability to nimbly respond to changing market tastes, then in each case the supply chain must be configured to suit—in terms of its processes, in terms of its organization, in terms of its infrastructure, and in terms of the systems that operate it. Fig. 2 depicts this.

Therefore, the first consideration in creating resilient supply chains is ensuring a clear strategic alignment between the organization's competitive strategy, and the supply chain. Not doing so risks either having a supply chain that is not synchronized with the goals of the business, or—importantly from a vulnerability point of view—a supply chain that is riskier than it needs to be, in order to support the goals of the business. An example of the latter would be a long supply chain stretching back to factories in China, incurring transportation-related risks, on the mistaken assumption that a low product cost was of overarching importance. Dell, Apple, and fashion firm Zara all stand out as businesses with supply chains perfectly aligned to their own—very different—business strategies.

Engendering Supply Chain Agility

To reduce the overall risk of a supply chain, supply chain agility is critical. Again, supply chain agility needs to be reflected in the supply chain's processes, infrastructure, information systems, and organization. Agile supply chains have a number of distinguishing characteristics. They not only need to be network-based, but they also need to be market-sensitive, with highly integrated virtual and critical processes. Agile supply chains need to synchronize both supply and demand, in order to respond quickly to both volume and variety changes. In addition, agile supply chains need to be able to adjust output levels quickly to match market demand, and to be able to switch rapidly from one variant to another.

Central to the achievement of agility is an understanding of what has been termed the “three Ts of highly effective supply chains”—*time, transparency, and trust*. Each is interrelated with, and dependent upon, the others. Understanding the **time** dimension of the supply chain enables organizations to gain transparency into what is happening within the supply chain; when supply chain participants know what is happening, confidence builds due to the resulting **transparency** and **trust** that then develops between all the players in the supply chain. Moreover, a virtual circle develops; trust engenders a greater understanding of the time dimension, and hence greater levels of transparency and then trust arise.

Where to start? It is often easier to begin by simply mapping the supply chain with respect to time. Once the time dimension is understood, then it is relatively straightforward to plot relationships such as demand with respect to time, processes with respect to time, or inventory holdings with respect to time. This then helps to both generate transparency and build an understanding of the key issues involved in the supply chain, further cementing trust.

Figure 2 Effective supply chain design.

Establishing Collaborative Supply Chain Relationships

To create a truly resilient supply chain structure, relationships are key. As Martin Christopher has noted, supply chains—and hence supply chain management—can be defined in terms of relationships: *“Supply chain management can be defined as the management of upstream and downstream relationships with suppliers, distributors, and customers to achieve greater customer value-added at less total cost.”*

Defined in this way, it becomes abundantly clear that these relationships must be actively managed, if the overall supply chain is to operate effectively. Organizations often underestimate the importance of dedicating resources to the management of relationships, especially in the upstream supply chain. Nevertheless, in real-life case studies of supply chain resilience, the quality of supply chain relationships, and companies’ investment in the requisite resources, often stand out as important contributory factors.

That said, businesses cannot build close collaborative relationships with *every* link in the upstream and downstream supply chain—and certainly not all at once. Some degree of prioritization is necessary. While individual circumstances will differ, logic suggests that the closest links should be forged with a combination of the largest suppliers, customers and partners, as well as those suggested by appropriate risk and resilience audits, even if the trading relationship is not especially significant in monetary terms. A case in point: supply chain risk buried within its tier-2, tier-3, and tier-n components.

After 2011 Japanese earthquake and tsunami, for instance, car manufacturer BMW’s first reaction to the disaster was to assume that it would be unaffected, as it had no suppliers in Japan. But it soon discovered that some critical tier-4 semiconductors came from North-eastern region of Japan. And on probing more deeply, the company then discovered several more instances of supply chains terminating in North-eastern Japan—in some cases, to factories that were the sole source of the components and materials in question.

Renesas Electronics, for example, the world’s largest manufacturer of automotive microcontrollers, was forced to cut production by 70%, with production shifted from its badly-damaged Naka wafer fabrication factory in the Japanese coastal city of Hitachinaka to a number of other sites around the company. Altogether, output was suspended at seven of the company’s 22 plants, with the worst affected remaining off-line until July—four months after the disaster.

Just as businesses cannot build close collaborative relationships with every link in the upstream and downstream supply chain, neither can businesses build equally deep collaborative relationships with every supplier. Inevitably, some relationships will be—and will need to be—deeper than others. In a spectrum of possible relationship types stretching from “arm’s length partnerships” through to “virtual vertical integration,” some selectivity is required.

Again, relative exposure to supply chain risk acts as a useful lodestar. Often, when organizations fully recognize the resource implications of managing highly collaborative relationships, it is not uncommon for them to take a more pragmatic view of relationship building. A natural priority: begin by identifying those relationships that could put the supply chain at risk, and invest scarce resources there first.

Finally, it can be useful to consider relationships with competitors. Collaboration between competitors is not so bizarre a notion as one might expect: clearly, those businesses with supply chain challenges and requirements that will be closest to a given business’s *own* supply chain challenges and requirements will generally be its competitors.

Often, the goal is cost reduction—or, increasingly, benefits allied to cost reduction, such as carbon reduction or other societal benefits. But there can be a supply chain risk dimension, as well. Automotive manufacturers PSA Peugeot Citroën and Toyota, for instance, shared component development across their Peugeot 107, Toyota Aygo and Citroën C1 models, potentially creating dual-sourcing possibilities.

Logistics possibilities exist, too. In the motor industry, for instance, tire, battery, and exhaust system manufacturers and distributors must deliver to the same dealerships and aftermarket retail outlets. In the grocery industry, grocery manufacturers must deliver to the same supermarket regional distribution centers, wholesalers, and retail outlets. In such circumstances, collaboration—sometimes dubbed “coopetition”—can make a lot of sense. To the extent that such arrangements provide access to a “backup” delivery option, or a larger pool of delivery resources, or make it possible to leverage the increased volumes and select a higher-quality and more resilient transport provider, then an element of supply chain de-risking clearly exists.

Fostering a Culture of Supply Chain Risk Reduction

Culture has been defined as “what we do or how we act, in the absence of instructions.” For businesses to develop maximally resilient supply chains, it is important that an effective culture of supply chain risk is fostered. Only in that way will supply chain risk be front-of-mind each time a decision relating to the supply chain is made. In other words, rather than supply chain risk—and supply chain risk reduction—being considered separately from other supply chain-specific considerations, the supply chain risk dimension is considered alongside, and as a part of, any ongoing supply chain deliberations.

This is not necessarily easy or straightforward. Supply chain strategies are generally couched in terms of issues such as cost-to-serve, price, responsiveness, service levels and inventory holdings. When managers are targeted and incentivized upon such things, their goals are very explicit, and an implicit impact on supply chain risk may not always be welcome. Nevertheless, if managements are serious about supply chain risk reduction, it is necessary to constantly ask questions such as:

- How will this action impact on the risk profile of the supply chain?
- Will this action make us more vulnerable to disruption?
- Will this action improve or detract from our resilience?

In moving to this way of thinking, it is a blunt fact that risk—and risk reduction—are often very intangible notions when set against such things as cost, price, and inventory levels. In terms of cost, for instance, the impact of sourcing a particular component from (say) China can be very clear. Far less clear will be the impact on supply chain risk. Nevertheless, a serious commitment to supply chain risk reduction will require managements to give greater priority to risk reduction than they may do at the moment.

A serious commitment to supply chain risk reduction will also involve the organization at times transcending long-standing organizational boundaries. Proper consideration of supply chain risk rarely takes place within tight organizational limits: some element of cross-functional collaboration is usually required, albeit on an *ad hoc* basis. This is particularly true of the “supply chain continuity” or “supply chain crisis management” teams that can be created, so as to be quickly brought to bear on issues and problems as and when they arise.

During the UK’s September 2000 fuel crisis, for instance, which was brought about by striking tanker drivers, it quickly became apparent that food supplies were threatened and the military was partly mobilized to help in the distribution of fuel, so as to alleviate this. Quite simply, supermarkets were unable to deliver to their stores, either because products had not reached their distribution depots, or because they lacked the fuel to undertake the outbound distribution leg to the store. But some businesses fared better than others: supermarket chain Sainsbury, for instance, was able to activate a team of supply chain contingency planning experts, helping it to make day-to-day decisions that delivered a competitor-beating performance.

Finally, building a culture of supply chain resilience may involve overturning long-standing traditions and existing cultural norms. The supply chain disruption caused by the Japanese earthquake and tsunami of 2011, for instance, resulted in considerable introspection among automotive manufacturers, both within Japan and overseas. Long an advocate of single-sourcing, Nissan began mandating that suppliers’ business continuity plans should include an alternate sourcing capability—in other words, the ability to seamlessly switch output to an alternative facility in the event of disruption at the primary facility. Toyota and BMW, for their part, reckoned to have learned important lessons about supplier transparency and openness in terms of supply chain mapping and sourcing visibility—including, in Toyota’s case, lessons regarding the advisability of modifying its product development processes so as to make it easier to use alternative parts.

Conclusion

For the most part, supply chain disruption happens with little warning. Even extreme weather—think 2017 Hurricane Harvey, for instance, which was the second-costliest tropical cyclone on record, inflicting a reported \$ 125 billion in damage—provided only a few days’ notice of potential disruption. So, for a resilient supply chain, forward planning is a key. While planning and preparation for a specific event is rarely possible, planning for disruption in general is certainly possible, as is planning for specific categories of events. Virtually every large retailer, for instance, will have a “playbook” for how to deal with product recalls or the collapse of a major supplier. In short, the time spent by organizations thinking through the options and understanding the risk profile of the supply chain is an important investment that will protect the organization’s performance.

That said, it is important to realize that such contingency planning is planning in the context of today’s organization: in other words, how should *today’s* organization respond to disruption, should it occur? But detailed planning—however extensive—has natural limits, and can only take an organization so far. “*No plan survives contact with the enemy*,” is how nineteenth-century Prussian military commander Helmuth van Moltke described these limits. “*Everyone has a plan—until they get punched in the face*,” said boxing champion Mike Tyson, more prosaically. Real resilience demands something else.

In short, as this chapter has shown, it is better to create resilience by reshaping the organization’s response to disruption, so that it is inherently better able to react and recover. With an organization that is equipped with the right culture, the right chain relationships, the right level of agility, and the right supply chain design, that is eminently possible.

Acknowledgment

I would like to thank my colleague Dr. Malcolm Wheatley, Visiting Fellow, Centre for Logistics, Procurement and Supply Chain Management for researching a number of the examples and cases utilized in this chapter.

Appendix A: Case Study

On Monday 3 February 1997, Toyota announced that all its Japanese assembly lines had been brought to a halt. The problem: a devastating fire the previous Saturday, at a plant belonging to one of its suppliers, Aisin Seiki. The company was Toyota’s only supplier of brake fluid proportioning valves (P-valves), which were used right across the manufacturer’s model range. With just half a day’s stock in hand, it was just a matter of hours before Toyota’s assembly lines ground to a halt—closely followed by those of the rest of its supplier base. Gloomy prognostications predicted that production would be halted for weeks; consumed within the blaze were the transfer lines used to manufacture the P-valves, along with other special-purpose machinery and drills.

Instead, P-valve deliveries to Toyota resumed just three days later, rolling off temporary lines hastily set up by a tiny second-tier Aisin supplier, Koritsu Sangyo. By the following Friday, production was back up to 90% of normal levels, reaching 100% on Monday

10 February, exactly a week after the fire. In all, some 62 firms found themselves manufacturing P-valves: 22 of Aisin Seiki's own suppliers, Toyota itself, 36 Toyota suppliers, and a number of independent businesses—including a sewing machine manufacturer, Brother Industries, which had never previously manufactured vehicle components. Also involved were around 150 other businesses, including 70 machine tool manufacturers, drill manufacturers and various suppliers of fixtures and gauges.

Impressively, the whole thing was coordinated by a four-team "emergency response unit" communicating with suppliers by fax machine and phone, distributing engineering drawings and specifications and liaising with materials suppliers. After the event, recognizing their achievement, Aisin Seiki published a booklet containing the lessons learned, making it available to its supplier network and all the businesses that had participated in the recovery effort.

Defining Safety and Security

Transportation professionals measure their performance according to: (1) business development, that is, commercial success, and (2) ensuring safe and secure operations, that is, the ability to prevent, eliminate, and recover from safety and security risks. While these terms are used interchangeably, in fact safety differs from security.

Transportation safety risks pertain to a company's ability to protect its operations from nonintentional, yet harmful elements, such as:

1. natural disasters or weather conditions, for example, hurricanes, flooding, earthquakes;
2. machinery breakdown, operational malfunction, technological failures, loss of structural integrity, construction vulnerabilities, etc.
3. human factors, that is, human error, fatigue, negligence, lack of situational awareness, unintentional damage, etc.

Transportation security involves risks of deliberate attacks aiming to compromise transport networks. Security risks are driven either by terrorist motives (i.e., nationalist, religious, or sociopolitical) or by financial motives. Security threats include terrorist attacks, vehicle hijacking or sea piracy, cargo theft, cyber warfare, money laundering, contraband, human or narcotic trafficking, and others (Burns, 2015).

While security attacks entail intentional damage, they are further categorized based on the nature of the motive:

1. Terrorism-based attacks are triggered by ideology based on religious, political, or social differences. Terrorism aims toward the destruction of life, property and the environment, aiming to instigate fear and social turmoil.
2. On the other hand, criminal-based attacks are driven by financial motives and the goal of profiting through illegitimate activities. Hence, criminals do not destroy property, but steal, hijack, or use transport for illegitimate activities such as contraband, money laundering, human trafficking, drugs and weapons trafficking, among others (Fig. 1).

Over the past years security investigations have associated terrorists with criminal networks, as part of larger, more intricate supply chains. This means that the funds generated from criminal activities, often end up being used by terrorist groups. For example, connections have been verified between religious fanatic groups and sea piracy, gun smuggling, and money laundry activities. Cyber security incidents have also revealed associations between hackers requesting ransom fees and the financing of terrorist groups.

The Human Factor in Security and Safety

We live in an era of unprecedented technological innovations, many of which were designed to strengthen corporate safety and security systems. Despite the high-tech achievements, it is still the human factor which plays a pivotal role in attaining a successful safety and security strategy (Burns, 2014).

The human factor plays a significant role in security and safety: Namely, there are two distinctions in security risks: (1) humans are motivated by ideology, hence commit acts of terrorism, or (2) humans are motivated by financial or commercial gains, and commit criminal acts such as money laundering, contraband, human trafficking, smuggling of weapons or narcotics, and others.

In the case of safety, while unintentional, the human factor still plays a critical role: human-driven factors are typically focused on negligence (including poor operational handling or inadequate maintenance leading to wear and tear); lack of situational awareness (such as failure to identify or act upon signs of an existing or potential safety threat); but also fatigue, lack of training, lack of familiarization with the facility or equipment, and so on.

The degree of familiarization with the premises, the technologies, the processes is another important factor. Surveillance cameras may be installed or cargo scanners may be used. However, it is the human element, that is, the operators of the respective equipment which can make a difference. The more familiarized company employees are, the stronger their defense is against safety and security threats. This is the reason that pertinent regulations request employees' familiarization as a prerequisite.

Risks and Vulnerabilities

Although incidents may occur unintentionally in the case of safety, and intentionally in the case of security, what is common is the fact that external risks manifest themselves in the presence of internal systemic vulnerabilities. In the case of safety, a risk will coincidentally be triggered due to a weakness or exposure. In the case of security, the perpetrators will intentionally and meticulously search for a systemic vulnerability and will plan their attack with the particular vulnerabilities in mind. What makes security risks more impactful, is the intentional attack of a systemic vulnerability (Burns, 2019b). Consequently, both safety and security risks cover the same physical, cyber, and supply chain realm, with the only distinction being the intentional damage in security versus the unintentional damage in safety.

Supply chain activities and operations are categorized according to their risk factor, and the domain they encompass is distinguished into:

1. Physical, that is, focusing on the tangible assets, commodities, and aspects of transport.
2. Virtual, cyber, that is, focusing on the intangible assets, that is, data available on IT, cyber and cloud-based platforms.
3. Holistic, including the entire supply chain with all its transportation networks, and various companies.

For modern transportation companies to safeguard their systems and enjoy professional success, they must find the perfect balance between operational efficiency, and an impeccable safety and security track record.

The likelihood of increased safety and security risks depends on different factors. Safety risks increase as companies' resources diminish, and limited budget is available for repairs, maintenance and investment in the physical and cyber protection of their supply chains. On the other hand, security risks pertain to targeted attacks by entities with financial motives (such as cargo theft) or ideological motives (aiming to destroy a particular target). Hence, security threats are initiated by entities targeting healthy, prosperous, and critical segments of a nation's infrastructure (Fig. 2).

Figure 2 The levels of risk tolerance.

Figure 3 The stages of supply chain.

Figure 4 The Domino effect, or how a single threat can impact the entire supply chain. *Source: Burns. M.G.*

Transportation is driven by the laws of derived demand, which suggest that as passengers and cargoes increase, so does the demand for specific transport modes and geographical trade routes. Also, the growth of global population and the economy will urge the transportation industry to grow accordingly.

Transportation networks are components of intricate supply chains, where transport is the glue, or catalyst for commodities to move from one stage of the supply chain to the next (Burns, 2018a, 2019a). Modern transportation networks are highly complex and interactive, which suggests that when a single company takes risks, its supply chain partners are also influenced. This is a characteristic of the trade and transport industry: it is considered as the norm when complex networks function in an effective and efficient manner. However, any delay or malfunction becomes instantly noticed.

As seen in Fig. 3, each stage of the supply chain is interrelated. Hence, when a safety or security threat impacts a single stage of the network, all others are affected through the domino effect. To eliminate safety and security risks, transportation stakeholders and their supply chain partners must ensure supply chain visibility. The interrelation between the supply chain and the domino effect are presented in Figs. 3 and 4, respectively.

The transportation industry is a high-risk, high-profit realm, suggesting that companies often striving for higher risk endeavors, are likely to maximize business development, commercial and financial gains. This is a highly competitive, ever evolving industry, where companies establish supply chain networks with the purpose of taking risks that are not only acceptable, but also rewarding. Fig. 2 demonstrates the levels of risk tolerance, with the high risk area reflecting safety and security challenges, among other types of risks.

As a transportation network grows, risks may grow accordingly. As global population grows, the demand for trade and transport also grows, production grows, and both physical and cyber networks grow. On an annual basis, the volume of global trade exceeds 10.3 billion tons of cargo, with its value exceeding \$17 trillion. By 2030, the global trade volume is anticipated to reach 20 billion tons of cargo. In the United States alone, cargo exceeds 2 million metric tons, among which, there are 15 million TEUs (twenty feet equivalent units) of containers. According to the FBI, annual cargo theft statistics become alarming, ranging from \$15 to \$30 billion each year.

As defined by the FBI, cargo theft pertains to “the criminal taking of any cargo including, but not limited to, goods, chattels, money, or baggage that constitutes, in whole or in part, a commercial shipment of freight moving in commerce, from any pipeline system, railroad car, motor truck, or other vehicle, or from any tank or storage facility, station house, platform, or depot, or from any vessel or wharf, or from any aircraft, air terminal, airport, aircraft terminal, or air navigation facility, or from any intermodal

container, intermodal chassis, trailer, container freight station, warehouse, freight distribution facility, or freight consolidation facility” (FBI, 2015).

To mitigate this threat, the FBI’s Uniform Crime Reporting (UCR) Program was established with the purpose of gathering and analyzing cargo theft information to notify law enforcement and other federal and state agencies, as well as legislators, universities and the general public. The data is gathered and duly analyzed in order to promote general awareness of the growing size and consequences of cargo theft upon our national security, economy, and other risks (FBI, 2016; Burns, 2018b).

When it comes to the transportation mode selection, it is worth noting that maritime transportation is responsible for about 90% of global trade. This determines the transportation risks, considering that each transportation mode has its own distinct safety and security risks. In general, geography and route selection will determine weather conditions, but also the risks of piracy or terrorist attack. On top of the transport mode selection, the selection of supply chain partners will determine the type, likelihood and impact of safety and security risks.

An optimum transportation network is characterized by the uninterrupted flows of passengers and cargoes. When delays and bottlenecks are present, safety and security risks are likely to be present as well. For example, safety issues are manifested through mechanical or operational failures. Most important, in the case of security attacks, perpetrators intentionally select systems with high traffic, bottlenecks, and systemic delays. There is a close relation among delays and border security: as global volumes of trade and transport grow each year, the incidents of safety and security also grow.

Transportation is the glue which connects all the components of global and domestic supply chains. Therefore, any safety and security disruptions trigger the domino effect or ripple effect spreading throughout the entire supply chain. Hence, a single vulnerability point has the potential to damage the operational and financial performance of several partners within a supply chain. Cargo theft, contamination, damage or simply delayed delivery may lead to losses, product recalls, or cancellations and reorders. This in turn triggers losses caused by reverse logistics processes, insurance claims, and long-term disruptions in partnerships.

Modern companies adopt a proactive safety and security culture, aiming to control as many factors as possible, and thus eliminate risk. As a principal rule, the closer the cargo is to a company’s premises, the greater the control and protection from risk. While the company’s assets and cargoes are in motion, especially in long-term haulage, the higher the exposure and the lower the control.

In order to assess the true risks of safety and security, it is worth measuring the cost of an incident. In the aftermath of an incident, the company’s brand promise or reputation are tarnished (Burns, 2017). This can be measured in the stock market where the value of shares can drop dramatically. In medium or high-impact incidents, the stock value diminishes by 30%–60% within only hours or days after the incident.

From a safety and security perspective, each supply chain nodal point is the convergent node where illegitimate activities affect legitimate trade and transport, and economic development. Based on the assumption that knowledge is power, visibility helps notify transport networks of a particular threat occurring in a specific nodal point and hence protects the entire supply chain through the transfer of resources and the creation of contingency plans.

While a company’s safety and security managers focus on strengthening the vulnerabilities within their premises, they often neglect to conduct meticulous safety and security background checks on their network partners, contractors and employees. Hence, a frequent outcome suggests that companies are involved in safety and security incidents, not due to their own omissions or weaknesses, but due to their partners or contractors’ shortcomings. After all, it has been established that about half of the intentional systemic damages are caused by insiders. As a conclusion, companies should be aware that we are as weak as our weakest links.

Trends in the 21st Century

Over the past decades, there has been a shift in the safety and security risks from the purely physical realm toward cyber and broader, supply chain risks. In response, companies and governments are increasingly adapting their preparedness and defense strategies accordingly.

The multilayered approach is based on the Swiss cheese theory, demonstrated in Fig. 5, suggesting that an incident occurs when multiple vulnerabilities are aligned, enabling the safety or security risk to manifest. For this reason, modern companies and governments adopt the multilayered approach. As several complimentary measures are taken to safeguard a company’s safety or security, the risks are eliminated. For physical security, the multilayered defense includes surveillance cameras, uniform/armed guards, fences, walls, vehicle barriers, and other protective measures.

The 21st century holds tremendous opportunities for the transportation industry, based on the new technological paths: Artificial Intelligence (AI), Big Data, 5G networks, Blockchain, Internet of Things (IoT), Bullet trains, and the list goes on... It is worth considering that new technologies do not only serve as instruments for safeguarding our systems and leading to prosperity. The benefits that these new technologies offer to legitimate entities, can also be offered to security violators, such as criminal entities and terrorists, to support their own goals. Hence, the job of safety and security professionals is to explore the capabilities of each innovative technology used in their supply chain, and consider how these tools can be used in the hands of security violators.

Figure 5 The Swiss cheese model applied in transportation or how safety and security threat penetrate layers of our defense.

One of the many challenges, and opportunities of the transportation industries is to be able to quantify and evaluate the benefits of a proactive safety and security culture. One significant shift in the industry entails the customer-driven business development approaches.

The US Government has developed MSRAM, a security risk analysis tool used to assist in the prioritization and protection of Critical Infrastructure and Key Resources (CIKR). It is aligned with the goals of the US Department of Homeland Security, in alleviating terrorist attacks within the United States; minimizing our nation's vulnerability to terrorism, but also the pertinent consequences, including damages; facilitating the fast recovery, and promoting socioeconomic security and sustainability (Burns, 2014).

Safeguarding the global transportation network from safety and security threats, is not only beneficial to the company, but also to the client: it promotes loyalty, long-term partnerships, and builds the brand name. While this notion was becoming popular in the dawn of the 21st century, the 2008 global economic meltdown led some companies to place low cost as a key driver. Financial restrictions forced many companies to make strategic transport decisions driven more by cost-efficiency factors and less by safety and security considerations.

Every organization, be it public or private, is asked to allocate budget across two main objectives: First, business development for organic and financial growth. Second, risk management including safety and security risks. Funds and resources are allocated at the managerial discretion. The advantage of requesting funds for financial and commercial development purposes is that their performance metrics are easily defined, measured and therefore better justified. On the other hand, safety and security managers may find it hard to negotiate the increased allocation of funds to avert threats which may, or may not occur, as it may not always be feasible to measure unmaterialized losses, or the benefits of risk aversion. It may be hard to measure and quantify the extent of the risk that was averted or eliminated, or prove that the company's preventive action has totally deterred an incident.

Once the brand promise is compromised, business loyalty is the second intangible commodity which suffers tangible financial damage. Order cancellations, loss of clients, credit and payment terms, as well as insurance premium levels are some of the anticipated losses following a major safety and security incident. Companies in general are reluctant to publicize their incidents, even in cases where the safety or security problem is inevitable. Small and medium-sized companies with limited resources and recovery alternatives, are the ones being mostly impacted by safety and security threats. Many of these companies collapse every year, unable to cover the unexpected expenditure.

Companies can reap tremendous benefits by showcasing an excellent track record and their safety and security performance over a number of years. An impeccable record provides tremendous advantages in building a company's reputation in the present tense. However, companies can only benefit from an excellent record of compliance, until the moment a serious accident happens (Burns, 2017). A company may have an impeccable safety and security record for decades, yet this does not presuppose a more favorable public opinion should an incident occur. Companies should remember that fine reputation takes decades to build, hours to destroy, and forever to recover.

Conclusions

This article has established a theoretical and practical framework that transportation professionals can use when working on safety and security risk factors. The process of safety and security is multi-dimensional and proper risk management requires contingency planning with the consideration of selecting alternative trade routes, partners, technologies, markets, and overall contingent plans. Promoting a culture of safety and security requires ongoing, dedicated efforts and a sincere alignment with the company's safety and security mission and strategic goals. The company's leadership must be dedicated to building and nourishing this culture. All company employees and partners must be responsible, alert, trained, and accountable when implementing the company's safety and security strategy.

Definitions of Transportation Resilience

Resilience is commonly used to describe the ability of an entity or a system to bounce back to a normal condition after its original state has been affected by a disruptive event (Henry and Emmanuel Ramirez-Marquez, 2012). Since resilience was first introduced in the context of ecological systems by Holling (1973), there are a number of different opinions and definitions of resilience in various application domains. From the perspective of transportation, various types of research on resilience have also been conducted, aiming to figure out what transport resilience is, what kind of features a resilient transport system has and what capabilities it should have. As a result, there are a variety of definitions proposed for the notion of resilience, though some of them are similar, having overlaps with other relevant concepts such as reliability, vulnerability, robustness, and survivability. The resilience definitions applied by previous transportation-related studies are summarized in Wan et al. (2018). Even though the research foci of these studies are transport systems, they are conducted from different perspectives. A careful review of definitions of resilience shows that there is no universal description as to what transport resilience is or what the standard definition of it should be. However, most similarities and differences can be observed across these resilience definitions. The highlights of resilience definitions from previous transportation-related studies are analyzed as follows (Wan et al., 2018):

- The majority of research defines resilience as a kind of ability (or capability) of a system/network, belonging to a system/network's inherent nature.
- Almost all these definitions are given with a consideration of abnormal conditions such as shocks, disturbances, disruptions, or even disasters. This reveals that one of the core intentions of resilience is the performance of a system in the face of disruptive events.
- Different verbs (such as resist, absorb, maintain, withstand) are used to describe the resilience of a system when a disruptive event occurs. Among all the actions, "recovery" is considered as the most critical one.
- It normally requires a system to return back to a predisaster state or at least be close to it.

Taking into account such highlights from the definitions in the literature, it is proposed that the resilience of a freight transport network (FTN) is the ability to recover its function of delivering freight cargoes from origin to destination within an acceptable time and cost, after the occurrence of disruptions. In the meantime, it is noteworthy that transport resilience is a contextual based definition, requiring further analysis of its characteristics to find the best way to describe and measure it with reference to the stages of occurrence of disruptions.

Characteristics of Freight Transport Networks

Different terms have been used to describe resilience and its characteristics, including but not limited to vulnerability, adaptability, robustness, preparedness, redundancy, response, and recovery. Currently, there are only a few studies analyzing the similarity and differences in the application of such terms in the transportation arena. Here, the most commonly used terms when describing the features and connotations of resilience have been extracted from the literature, as summarized in Table 1.

As a crossdisciplinary concept, resilience has been studied in different research fields from various aspects, with emphases on one or several of its particular properties. Sometimes it is not sufficient to describe resilience by only using mathematical equations, especially in a more general situation. It will increase the difficulty for decision makers to understand and apply it

Table 1 Interpretations and analysis of terms related to resilience.

Term	Interpretation/analysis
Vulnerability	It is defined as the susceptibility to damage or perturbation—especially where small damage or perturbation leads to disproportionate consequences. It is also regarded as the property of a transportation system, which may weaken or constrain its ability to endure, handle and survive threats and disruptive events that originated both within and outside the system boundaries.
Adaptability (or adaptive capacity)	It is defined as one of the functions of a resilient system, reflecting its flexible ability to response to new pressures. Its main features lie in its response to changes reflecting the dynamic nature of complex systems.
Robustness	It is the property of being strong, healthy, and hardy. Thus it is generally defined as the ability to withstand or absorb disturbances and remain intact when exposed to disruptions.
Flexibility	It's the ability of a system to respond to shocks and adjust itself to changes through contingency planning after disruptions. It is also referred to as an ability to reconfigure resources as well as to cope with uncertainties. As such, connotations of flexibility are opposite to that of robustness, which emphasizes the ability to endure these changes rather than to adapt to them.
Reliability	It is generally defined as the probability that a network remains operative given the occurrence of a disruption event. It can be either a pre-disruption or postdisruption metric for measuring system performance.
Recoverability (or the ability to recover)	It has been discussed the most in terms of the research of transportation resilience. It is defined as the ability of a network to recover functionality in a timely manner. It is regarded as an important feature of secure and highly functioning transport networks.
Redundancy	It indicates the ability of certain components of a system to take over the functions of failed components without adversely affecting the performance of the system itself. In the context of transportation, redundancy is generally viewed as the existence of optional routes between origins and destinations. It is commonly accepted that the more redundancy a system has, the more resilient it will be.
Survivability	It is generally defined as the ability to withstand sudden disturbances while meeting original demands. Survivability techniques have been considered as an access to mitigating the vulnerability of a network or system.
Preparedness	It refers to “ <i>prepare certain measures before disruption happens</i> ”, and it enhances the resilience of a system by lessening potential negative impacts from disruptive events. It can be subdivided as emergency preparedness and response preparedness.
Resourcefulness	Resourcefulness is defined as the availability of materials, supplies, and crews to restore functionality in the study of transportation resilience. Resourcefulness was treated as one of stabilizing measures in resilience. It indicates the level of preparedness in effectively resisting an adverse event.
Responsiveness	It is regarded as an important factor to the resilience of transportation networks. Similar to redundancy, responsiveness factors of a system may also increase the costs although it is able to improve the service level of a system.
Rapidity	It is a well-studied concept in the “ <i>resilience triangle</i> ”, a framework that has been applied in civil infrastructure for decades. It contains a hidden meaning of recovery, but with more emphases on the speed to recover. It affects the duration of reduced performance of a system.

in practice, and inevitably result in the neglect of parts of its properties in theoretical research. Thus Wan et al. (2018) concluded and expounded the key characteristics of resilience by using graphic representation. The hypothetical system performance of a resilient system under normal conditions and in the face of disruptive events are shown as Fig. 1, which attempts to incorporate as many characteristics of resilience mentioned in the literature as possible, and provides a general overview of performance of a time-dependent system.

For a transport system, performance can be understood as the service function it offers, and it is usually measured with operational metrics such as a component's capacity, traffic flow, and throughput. Overall, the performance with respect to the time of occurrence of a disruptive event can be divided into three stages: predisruption (t_0, t_e), disruption (t_e, t_r), and postdisruption (t, t_r) periods. From Fig. 1, it is observed that the resilience of a FTN is largely determined by reliability, redundancy, robustness, and recoverability (the 4Rs), as they measure the overall performance of an FTN in terms of how long it can perform without failing, what actions it will take in the face of a disruptive event, how much function will remain after being disrupted and how it reaches a new equilibrium.

Challenges in Research Methods and New Techniques Used in FTN Resilience Studies

In previous transport resilience studies, the most used methods are quantitative and include mathematical modeling, simulation, and their combination. It is often the case that simulation is used to validate the analysis of mathematical modeling. Qualitative studies involve surveys, case studies and conceptual work. Reviewing the previous methods used in transport resilience reveals that (1) there are a lack of empirical data when conducting transportation resilience studies; (2) natural hazards such as flooding and earthquakes are identified as predominant sources of external disturbances, particularly in qualitative analysis; and (3) resilience is often measured at a microlevel of transport nodes or links, with the support of a real case study, thus lacking a systematic analysis from a whole transport network viewpoint. For instance, in terms of the applied context, ports attract the most qualitative studies, largely because of their crucial roles in FTNs. However, the issues as to how the resilience of a port affects the resilience of the wider

Figure 1 Schematic of performance of a resilient system. Source: Reproduced with permission from Taylor & Francis Ltd (www.tandfonline.com). The original source of publication is from Wan et al. (2018).

FTN has yet to be answered. In light of the above, analyzing the resilience of an FTN requires addressing the following challenges with some urgency:

- How to quantify the resilience of freight transport with uncertainty in data? Quantifying the resilience of FTNs will be very beneficial in justifying the investment in new infrastructure through cost benefit analysis. However, traditional resilience analysis techniques that are capable of dealing with disruptions by classical risks will probably be insufficient to tackle emerging ones associated with climate risks, against which objective failure data are often not available to aid the relevant analysis. In a recent study, Wu et al. (2019) quantified the resilience of maritime shipping networks under natural hazards based on the concept of resilience triangle. In the study, a resilience index was proposed according to Fig. 1, which was defined as the ratio between the area of the changed/influenced performance and the initial status with respect to the total recovery time needed. However, the recovery cost was not considered in their research, which still remained as an important issue to be dealt with.
- How to measure the resilience of transport nodes and links from a global FTN perspective? In the design and management of transport networks, it is crucial to understand which components are the most important to the resilience performance of the whole network, and are thus vulnerable when facing disturbances. However, previous relevant studies focus more on the risk-based resilience analysis of individual segments (e.g., road, port, and shipping) of large multimode FTNs (e.g., international container supply chains). Few studies have been found to measure the vulnerability of components considering the resilience of the whole FTN (e.g., Liu et al., 2018). It is often the case that marginalized nodes (e.g., ports) in a large FTN are exposed to high risks but have poor resilience due to economic constraints compared to more centralized nodes. However, their impact to the whole network resilience is relatively low. It is therefore essential to take into account both local internal risk and global external safety impact when measuring FTN resilience.

An Advanced Method to Measure the Risk-based resilience of FTN Components Facing High Uncertainty in Failure Data

Conventional risk assessment approaches [e.g., quantitative risk assessment (QRA)] which have been widely used to carry out risk analysis in many sectors are not well-suited to dealing with emerging risks (e.g., climate risks) in which, as mentioned earlier, a high level of uncertainty in data exists. Due to the serious scarcity of historical/statistical data, the assessment needs to be conducted using subjective judgments for the purpose of prioritizing climate risks and rationalizing the allocation of adaptation resources. This may comprise various types of uncertainties including, but not limited to, “fuzziness” and “incompleteness.” An effective way to cope with such imprecision is to use linguistic assessment. However, such linguistic descriptions define risk parameters to a discrete extent

so that they can at times be inadequate. Fuzzy set theory has the ability to model such subjective linguistic variables and deal with the discrete problem. In Yang et al. (2018), new risk parameters such as *timeframe* (T), *likelihood* (L), and *severity of consequences* (S) are modeled by fuzzy linguistic terms to calculate the climate risk index. The risk parameters are tested through a survey, with the possibility of adding or eliminating parameters. Through the survey the linguistic variables/grades used to describe each identified risk parameter are defined and used to evaluate the risk levels of climate risk. A novel climate risk assessment model is developed by combining fuzzy logic and Bayesian network approaches in a complementary way, in which a fuzzy rule based method is employed to construct the collected information (i.e., climate risk parameters and their associated grades) through fuzzy belief IF-THEN rules, while a Bayesian reasoning mechanism is used to aggregate all relevant rules for facilitating risk calculation and realizing the climate risk evaluation. The theoretical foundation of the new climate risk model shares the same principle as with a fuzzy rule based Bayesian reasoning (FuRBaR) approach, which was originally presented in Yang et al. (2008).

The new climate risk model has been reinforced by expanding the risk parameters to a more detailed level [e.g., the use of economic and environmental damage to model *severity of consequences* (S)] in which they can be better evaluated by using both objective data and subjective judgments. It strikes a new thought on the solutions to this issue in future. Climate risk parameters can be further broken down to a level where data from other climate models (e.g., sea level rise) can be used as the input and integrated into the proposed risk model. In the meantime, the risk parameters will be examined to find their correlations with climate change risk indexes (CCRIs) (e.g., temperature), which can be measured using historical or quantitative objective data. By doing so, the objective measures on the CCRIs can complement the expert evaluations based on the defined linguistics variables to improve the analysis accuracy. Finally, sensitivity analysis can be conducted to investigate the resilience of the investigated FTN component(s) to different levels of disruptions of the prioritized climate risks.

Quantitative FTN Resilience Analysis from a Global Network Perspective

Analyzing the resilience of any FTN requires the consideration of both internal risk levels of FTN components (e.g., shipping and ports) and their external safety impacts on the global performance of the network. This is because the high risk of a transport node or link does not necessarily indicate a high impact on the resilience of the whole FTN, as its impact also depends on the specific role it plays in the whole network. Conventional resilience analysis of a transportation network often compares the variation of certain indices related to network performance, before and after the removal of node(s) and link(s). In the context of FTN, the removal of a node implies the shutdown of a port/dry port or an inland depot, such as a regional distribution center, while the removal of a link refers to the changing of freight transport service configurations. Here, the concept of network vulnerability is often used to describe the degradation of network performance due to a random or selected removal of nodes and links (Liu et al., 2018). Random removals imply the disruptions that may occur on any node or link in a random manner. They are caused by natural disasters or unexpected accidents. Selected removals (e.g., deliberate attacks) will prioritize certain target nodes and links following a strategy of degrading the network performance in the fastest way possible. Such priority is obtained by studying network topology features, only without the incorporation of the selected nodes/links' resistance ability to the attacks, which are often denoted by its internal risk levels. In other words, in traditional transport network resilience studies, there was a strong assumption that the effort to remove the selected nodes/links when facing deliberate attack is identical. Such an assumption becomes error-prone in the context of an FTN, in which ports and shipping routes often have different resistance ability to external attacks/disruptions. In this study, we use the internal risk level of the nodes and links to express their resistance ability. The higher the risk level is, the lower the resistance ability. While the internal risk estimates of FTN components are obtained from traditional QRA or the advanced method presented in the fourth section, the focus of its resilience analysis is shifted onto: (1) how to expand the network topology measures (e.g., centrality analysis) to describe the external impact of individual components on the performance of an FTN and (2) how to combine the internal risk estimate of a component with its external impact.

To measure the impact of individual nodes in a FTN, a model containing degree centrality, node strength centrality, betweenness centrality, and closeness centrality is developed based on the Borda Count method (Liu et al., 2018). The impact of individual nodes based on Borda Count is normalized and then used to calculate the impact of any link by the multiplication of the impact values of the two nodes it links. The impact of a node/link is then used to express their importance/weights. To combine the internal risk estimates of a node/link and its external impact, an evidential reasoning (ER) approach (Yang et al., 2018) is used because of its advantages of accommodating both quantitative and qualitative data and the relative ease of conducting sensitivity analysis by assigning a zero weight to any eliminated nodes and links of the FTN. The quantitative data refer to the risk estimates of certain nodes/links by QRA, while the qualitative data mean the risk results by FuRBaR in a form of belief based linguistic terms. The quantitative data, if any, can be converted into qualitative data using the rule base in the ER approach. As a result, the performance of any investigated FTN can be obtained, which reflects the resilience of the FTN during normal operational environments. Next, the internal risk level of any component can be adjusted to test its impact on the performance of the FTN through sensitivity analysis. Compared to previous studies of eliminating nodes/links, the new model allows the analysis of the impact of the partial functioning of a node/link (due to a particular disruption) on the resilience of the FTN. The difference between the reduced performance after the sensitivity tests and the original performance is used to express the resilience of the network to the impact of a particular disruption on a node/link. Currently, the external impact is based on static centrality analysis without the incorporation of the freight throughput of any node/link. This prompts a new research direction in the future to investigate how different freight throughput affects the resilience of an FTN.

Conclusions

This article answers the questions on what TFN resilience is, what characteristics it should have, and how to build and measure TFN resilience. Furthermore, the research challenges and useful remarks on resilience measures in TFN systems are analyzed and discussed. The relevant findings and implications are concluded as follows:

- *Definition of contextual resilience.* There is, as yet, no universal and widely accepted definition of transport resilience. It is left to be argued if, as an interdisciplinary concept, TFN resilience requires a universally accepted definition, and if resilience should be utilized in different ways depending on specific applications at hand. Nevertheless, it is essential and significant to propose a specific definition of resilience to define its study scope, research methods, and required data before applying it within certain domains, such as disaster resilience, and climate change resilience.
- *Quantitative resilience analysis.* The majority of the resilience studies define it as an ability of a system that can absorb disruptions, while some describe it as a function or metric to measure the system performance against disruptions. In theory, both ability and metrics can be quantified. In fact, from a risk perspective, if resilience measures cannot be assessed quantitatively, the resilience management system does not motivate industrial companies/local authorities to adopt them, possibly because their effects are not visible in a state-of-the-art risk assessment. Risk-based resilience of TFN components with respect to particular emerging risks (e.g., climate change) can be coped with by incorporating subjective data based on advanced uncertainty models such as FurBar. TFN system resilience can be measured by incorporating both internal risk estimates of individual nodes/links with their external impact based on an ER approach. The recommended evaluation of the external impact should take into account dynamic cargo throughput in future.

In general, attention needs to be given to the application of resilience in the early design of the associated infrastructure by the introduction of a “design for resilience” concept. It is necessary to develop and standardize a framework for quantitative resilience analysis that can incorporate the features of transportation resilience, consider the different phases of a disturbance striking the system and evaluate resilience from a global systematic perspective, connect resilience with safety management, and properly cope with the uncertainty in both qualitative and quantitative data. It is required to enable this framework, not only to assess the resilience status of existing transportation systems to identify vulnerable parts and prepare for unpredictable disasters, but also in the system design process, to provide a reference for optimal decision making for the development of transport infrastructure, on issues such as route planning and key infrastructure maintenance and renewal.

Introduction

Emissions from freight transportation is one of the largest sources of industrial emissions, and it is growing. Yet, it receives very little attention from consumers or in the popular press. As a result, we are missing opportunities to make significant progress that can simultaneously reduce emissions, reduce fossil fuel use, and reduce costs and slow climate change. A fundamental question in logistics and transportation is “what transportation mode should I choose?” The modal choice depends on many factors, such as when the item is needed, accessibility to that mode of transportation, cost of shipping, item characteristics such as weight, any special handling required, value, fragility, and so forth. Another important criterion that is often overlooked is that of the environmental impact of each mode, and the carrier selected within the mode. The purpose of this paper is to explore the environmental impact of freight transportation in general to understand the environmental and other performance characteristics of each mode, explore the progress that has been made in environmental transportation, the barriers to further progress, and how to move forward in research and in practice.

The Impact of Freight Transportation on the Environment

The greenhouse gas (GHG) emitted by burning fossil fuels has a significant, negative impact on the natural environment and on human health. GHG from transportation emissions includes carbon dioxide (CO₂), methane (CH₄), and nitrous oxide (N₂O). It also includes sulfur and particulate matter that are harmful to human health and the natural environment. These are well-known negative impacts documented by the World Health Organization, and other highly credible international organizations ([World Health Organization, 2018](#)). The implications are staggering: 9 out of 10 people globally live with air pollution, which takes approximately 7 million lives annually. Ninety percent of children breathe toxic air, creating lasting damage to their developing lungs, increasing rates of asthma, emphysema, and other health-related breathing problems, increasing health-care costs, and reducing quality of life.

In addition, air pollution is influencing a faster rate of climate change. This contributes to extreme heat, more natural disasters, food insecurity, and more premature deaths, to the elderly and children in particular. Freight emissions is one important and significant source of GHG that can be reduced, with resulting reductions in the negative impact of emissions ([Environmental Protection Agency, 2017](#)).

The Contribution of Freight Transportation to GHG Emissions

Understanding the magnitude and impact of freight emissions is extremely complex. Various reports break out emissions in different ways, some including all passenger and freight transportation, some including only domestic freight, and some including only international shipping. In addition, they include different assumptions about the vehicle types, weights, and use kilometers or miles, so comparisons are challenging. In spite of these complexities, several things are clear from the data. First, freight transportation relies heavily on the burning of fossil fuels, which generates a high level of air pollution and associated environmental damage. Second, while each country includes its domestic transportation impacts in its total GHG emissions, international aviation and marine emissions are reported separately, as no country is willing to claim these. These are not included in the Paris Climate agreement, but are managed separately by the International Civil Aviation Organization and the International Maritime Organization (IMO). Thus, country-level emissions are understated. Third, with growth in international trade and travel, international transportation emissions of all types, including freight, are large and increasing. A recent study by the International Council on

Table 1 Estimated freight emissions included in US total transportation emissions^a

Category	Percentage
Heavy duty trucks	21%
Pipelines	2%
Rail	1.9%
Aviation/aircraft	3.3%
Domestic ships/boats	2.1

^aAll estimates are from the EPA Fast Facts 1990–2017, except aviation is estimated from the EDF Green Freight Handbook.

Clean Transportation (ICCT) indicates that if treated as a country, the impact of international freight shipping would be the sixth largest emitter of energy-related CO₂ in 2015 (Olmer et al., 2017).

Most people do not spend much time thinking about the environmental impact of transportation, or the differences in environmental impact between modes. Companies do not provide insight into the differential environmental impact of overnight shipping (probably air) versus shipping that takes a couple of days (probably truck), more than a week (rail and truck combination), or over a month (intermodal—ocean freight plus some domestic mode such as truck or rail). Because consumers do not demand this visibility, companies do not offer the visibility. Most companies do not spend a lot of time trying to minimize the environmental impact of freight. They focus on getting a low cost while meeting their customers' delivery expectations.

Good data are available for the impact of freight transportation for the United States from the environmental protection agency. This is used for illustrative purposes here to gain an understanding of implications of freight emissions (Table 1).

This means that freight transportation is around 8.8% of total GHG emissions in the United States, excluding international ocean and airfreight shipping. It is a significant amount from one source. Ocean shipping, the impact of which is not acknowledged by individual countries, adds an additional 2%–3%.

Given what we know about the science of climate change, it is important to work on reducing the impacts of freight transportation. It is possible to reduce the amount of transportation by working smarter, and to reduce the impact of transportation by shifting to less polluting modes, and working on reducing the impact of existing transportation. These ideas are presented in further detail later.

Transportation Impact by Mode

While the earlier detail provides information on the impact of modes based on their usage, it does not give insight into the impact of each mode per ton-mile. A few things to keep in mind when considering transportation impacts are as follows:

- In advanced economies, virtually all consumer goods travel via truck at some point on their path to the ultimate consumer.
- All ocean freight involves very long distances. In addition, while the CO₂ emissions of ocean freight may look relatively low per ton-mile, ocean freight has additional negative impacts not captured within GHG accounting.
- The figures are averages, and the choice of a specific carrier within a mode, as well as how fully utilized the capacity is on a given trip, results in significantly different impacts.

Table 2 summarizes the relative performance of the major transportation modes according to their key performance characteristics.

From reviewing Table 2, several things should be clarified:

1. Air and motor carriers provide the shortest and most reliable transit times.
2. The faster the shipping mode, the worse the environmental footprint per ton-mile. This makes sense, as these modes are more expensive because they burn more fossil fuel, and the fossil fuel consumption directly impacts the emissions.

Table 2 Relative modal performance

Performance criteria*	Motor (truck)	Ocean shipping	Railroad	Air	Pipeline**
Cost per ton-mile	4	2	3	5	1
Speed/transit time	2	4	3	1	5
GHG***	4	2	3	5	1

* Ranking is based on 1 as the best (fastest, cheapest, lowest emissions) and 5 as the worst.

** Pipeline considers the impact of transmission.

*** Cost and GHG rankings are based on performance per ton-mile.

Table 3 Estimated average emissions performance by mode in gram per ton-mile^{a,b}

Mode	CO ₂	NO _x	PM ₁₀	PM _{2.5}	SoX
Truck	210	1.145	0.047	0.045	Not available
Ocean ^c	11	0.158	0.025	Not available	Very high
Rail	22.94	0.427	0.012	0.012	Not available
Air, short haul ^d	4,236	38.2342	0.250797	Not available	Not available

Intermodal	77.19	0.635	0.022	0.022	Not available
Barge ^e	17.48	0.4691	0.0117	0.0111	Not available

^aCalculations are in grams emitted per short ton (2000/lbs) of freight moved. No data on pipeline were available.

^bRail, truck air, and intermodal are from 2018 SmartWay Logistics Company Partner Tool.

^cBased on EDF data.

^dShort haul is 3000 miles or less.

^eFrom US Maritime Administration and the National Waterways Foundation (US MARAD), amended January 2017. *A Modal Comparison of Domestic Freight Transportation Effects on the General Public*. Prepared by Center for Ports & Waterways, Texas Transportation Institute (Table 10). Available from: <http://www.portsofindiana.com/wp-content/uploads/2017/06/Final-TTI-Report-2001-2014-Approved.pdf>; provided in 2018 SmartWay Logistics Company Partner Tool report.

3. Faster shipping is directly more expensive.
4. An increasing amount of freight is being moved by personal and light utility vehicles to support the last mile of e-commerce logistics for home delivery. The impact of this is not included in the transportation figures reported here.

The earlier detail provides the relative differences. What about the absolute impacts of the various modes? **Table 3**, derived from numerous sources, provides some initial insights.

These numbers can be a bit overwhelming and confusing. Most of us are not familiar with these units of measure. The figures are comparable to each other, because each reports the emissions impact of that mode for 1 ton of freight shipped 1 mile. To provide some insights, **Table 4** scales these numbers so that ocean shipping, which is the lowest in terms of grams per ton-mile for CO₂ is a base of 1 for each type of emission. In addition, keep in mind that they are estimates based on many assumptions and averages related to the exact technology used, the capacity utilized and more, and an individual carrier within a mode may perform quite differently: either better or worse.

Truck is the most common mode of domestic transportation in most cases. The impact of ground freight transportation is increasingly understated as more personal and passenger vehicles are being used for the last mile of home deliveries to end customers. In addition to the various types of emissions to air of trucks, they also negatively contribute to noise pollution, road congestion, traffic accidents, and deaths (Environmental Protection Agency, 2019).

Ocean shipping is the most important form of transportation for global trade. Not only is it essential for the movement of goods between continents, it causes significantly less impact in most emissions per ton-mile than does airfreight. Important exceptions to this are black carbon and sulfur dioxide. Inexpensive transportation is essential for efficient and competitive world trade. While transportation by ocean can be long, 20–40 days depending on the ports and seasonal congestion, it is also fairly consistent. Importantly, it is extremely inexpensive, costing around \$0.05–\$0.10 to get a piece of clothing from Asia to North America, less than the transportation of the item within North America. While all of this is good, ocean shipping does have some devastating, and little-understood environmental impacts that are extremely well summarized in the work by Walker et al. (2019).

The impacts of ocean shipping are difficult to study and difficult to regulate, as they are international in nature, not “owned” by any one government. Ocean transportation is regulated by the IMO. First, ocean transport of all types, including shipping, historically uses a very high-sulfur, low-quality type of fuel known as bunker fuel, accounting for about 13% of global sulfur-

Table 4 Relative estimated emissions performance by mode per ton-mile, ocean shipping as base^a

Mode	CO ₂	NO _x	PM ₁₀	PM _{2.5}	SoX ^b
Truck	19.09	7.24	1.88	0.045	0.0004
Ocean	1	1	1	Not available	1
Rail	2.09	2.70	0.48	0.012	Not Available
Air, short haul	385.09	241.99	10.03	Not available	Not available
Air, long haul	132.8	88.23	3.46	Not available	Not available
Intermodal	7.02	4.01	0.88	0.022	Not available
Barge	1.59	2.96	0.468	0.0111	Not available

^aOcean is set to 1 in each relevant category to make relative comparison.

^bShipping bunker fuel is 27,000 ppm sulfur versus about 10 ppm for vehicles, per Walker et al. (2019).

dioxide emissions. This fuel causes extreme outputs of sulfur-dioxide emissions, which is harmful to human and marine life. As a result, the IMO has mandated that as of 2020, ships must switch to marine fuel that is 0.5% sulfur, away from the 3.5% sulfur bunker fuel. This will raise shipping costs, which will ultimately be passed on to consumers. However, a report from Yale indicates that it will also save thousands of lives, as 70% of emissions from ships are said to occur within 250 miles of land, exposing millions of people to dangerous emissions. It is estimated that the move to cleaner fuel will reduce ocean shipping-related premature mortality by 34% (150,000 deaths that are primarily heart and lung-cancer related) and illness by 54%, (a reduction of 7.6 million cases of childhood asthma). Another alternative way that companies can reduce ocean shipping sulfur emissions is to switch to scrubbers. The problem with scrubbers is that they pull the pollution out of the air but must be cleaned and the waste from the cleaning must be disposed of. This is often done at sea, which has other negative implications. Switching to liquid natural gas (LNG) would reduce all sources of shipping pollution even more (IMO, 2019).

While it appears that the fuel emissions issue is finally being addressed in some measure, with more sensitive areas enforcing a 0.1% sulfur content in marine fuel, there are numerous other negative environmental implications from ocean shipping. Two-thirds of oil spilled during transportation happens on the ocean, and has ravaging, often long-term effects on many plants, animals, and birds. There are also spills of other hazardous materials, which are increasingly being transported by ocean. Garbage waste from ships is also a problem, though freight ships have few people compared to cruise ships. They are still allowed to discharge food waste and raw sewage at sea, which is certainly harmful to the marine environment. While there are laws about proper discharge of ballast water, we know that invasive aquatic species are transferred through the release of such water. This is very difficult to police. European green crab, zebra mussel, and Chinese mitten crab are some examples of invasive species that have been spread by ballast water.

While we think of noise pollution when we think of land-based travel and airplanes, we think of it less with ocean travel because of the distance ships travel from shore. Unfortunately, the noise pollution that ships create can be very destructive to marine species, even over long distances. Sound is used by most marine animals for everything from communication and navigation to reproduction and avoidance of predators and other hazards. Noise can create stress, behavioral change, and even death. Thus, while one aspect of ocean shipping, sulfur emissions, is being addressed, there are many more.

Rail is excellent for large, bulk shipments, usually traveling 500 miles or more. While it tends to be slower than truck and does not go door-to-door unless you have a rail spur, it has significantly less emissions and is cheaper. It is also less reliable. It is often used *intermodally*, combined so that trucking is used for final delivery. Combining it in this way can be cost-effective and better for the environment when shipments are not very cost sensitive. One of the biggest issues with rail is the noise that it makes, and the space that it takes. No one wants railroad tracks in their backyard. In the United States, the miles of usable rail track have dropped dramatically in the last 50 years. It is difficult to return rail track to use once it is out of service (Ellram et al., 2019).

Airfreight has the worst environmental emissions profile of any mode. It uses so much fuel on takeoff and landing that it is very expensive and very bad for the environment. In addition, not reflected in these figures, emissions released at higher altitude have a worse impact because the air is thinner. Thus, the true CO₂ impact of air is even worse than depicted in the table. Short haul is much worse than long haul due to the impact of the takeoff and landing, with fewer miles in the air to average out those impacts. One thing is certain: you do not want to live near an airport due to the high level of emissions that planes release on takeoff and landing, and also due to the noise pollution (McKinnon, 2018).

The bottom line is that companies need to be smart about using airfreight. When is it really essential in terms of retaining customer business, or in some cases shipping medical supplies or organs to save lives? From a cost and an environmental standpoint, it should be avoided except when it is essential. For example, some fashion companies such as Victoria's Secret ship their fashions by ocean in the pre-season. During peak season for an item, stock is replenished by air in order to meet customer demand before the season ends or tastes change. Dell computer, which used to rely heavily on air to ship its final products, has also reevaluated what it can forecast versus ship-to-order, and have dramatically shifted its freight shipments to ocean away from air, saving both money and the environment.

Barge can be very effective for the same types of freight as rail, but you do need a waterway to make it work. Barge is common in some areas of Europe, and for bulk commodity items in the United States, especially on the Mississippi River.

Reducing Freight Impacts

New technologies are emerging which could dramatically reduce the impact of freight emissions. Electrification of freight transportation could also drastically reduce noise pollution. Electric semitrucks for freight haulage are under development by numerous companies, with Tesla, Nikola Motors, Volvo, Kenworth–Toyota partnership, Daimler, and Thor all having models which are either being tested or underway. These still suffer from somewhat limited range and a lack of a good charging network, so these will not take over quickly. However, as they do come on board, their positive impact on noise pollution and emissions will be dramatic. Hydrogen trucks are also underway, but suffer similar problems. Still, these provide very quiet, potentially zero emissions offerings if they are charged by alternative energy.

Hydrogen and wind offerings are also under development for ocean shipping, with renewable energy and biodiesel alternatives also being tested for air. Solar and electrification experiments are also underway for railroads. These provide great options for reducing the damage from using fossil fuel. But these are evolving and will not be widely developed and implemented overnight. In

Table 5 Reducing transportation emissions**Technology**

- Purchase the most efficient and cost-effective technology for your transportation requirements.
- Install auxiliary power units so you can turn off the main engine when you are not moving.
- Install governors to limit the maximum speed to one that is efficient.
- Install GPS units to reroute out of bad traffic areas.

Company priorities

- Elevate the awareness of freight transportation impacts. Set goals for reduction and reward and publicize the achievement of goals.
- Use SmartWay certified or other environmentally certified carriers who use current equipment and know how to reduce their environmental footprint.

Educate and increase awareness

- Train your drivers of any mode to drive efficiently, and consider rewarding them for their efforts.
 - Turning off the engine (no idling) when stopped for more than a few minutes.
 - No sudden acceleration, which burns up a disproportionate amount of gas.
 - Driving at a steady and moderate speed.
- Join a green transportation initiative such as SmartWay (UA, Canada) or Green Freight (globally) to learn more about freight emission and techniques to improve freight efficiency.

Improve equipment planning and utilization

- Use intermodal transportation where possible.
- If you own your own fleet, utilize it where you can be efficient, and outsource your transportation to more efficient carriers in areas where you have limited volume and are no backhaul. Empty miles are not only expensive, they add to your environmental footprint by moving air.
- Work on improving your utilization of loads as much as possible. There are many ways to do this, including:
 - Look at your product configuration to make sure you are shipping in the most efficient way in terms of weight, space, palletization, and so on.
 - Redesign and reduce your packaging weight and size so that you can fit more in each shipment while also reducing packaging waste.
 - Plan your loads and routes so that they can be a fully utilized as possible.
- Continually revisit your logistics network design, loads, customer needs, and improve upon your transportation processes.
- Plan routes to avoid traffic at peak hours in congested areas.

Collaborate with others in your supply chain to reduce transportation emissions

- Consider your customer's true needs, and use less damaging, slower shipping by planning better. These means saving air shipments for emergencies only. Switch from truck to rail wherever possible.
- Talk to your carriers and customers about ways to improve your load utilization and get their ideas, including ways to better utilize backhaul capacity.
- Encourage your suppliers to reduce their freight transportation emissions and join organizations such as SmartWay.

the meantime, there are certain behaviors that firms who want to reduce their fossil fuel use and associated cost and environmental impact can implement. These are presented in [Table 5](#).

Following the approaches mentioned earlier can have a tremendous impact. For example, Walmart was able to more than double the efficiency of its freight fleet between 2005 and 2015, saving almost \$1 billion and avoiding 65,000 metric tons of CO₂. It is now focusing on the electrification of fleets and encouraging customers to combine trips and orders to reduce the impact of the consumer last mile pickup and delivery ([Walmart, 2018](#)).

Moving Forward

How urgent is the need to act and reduce emissions and other environmental impacts associated with decreased quality of human life? The fact of the matter is we cannot say with certainty. Climate changes over time due to natural shifts as well as man-made causes, and it is difficult to separate the effects completely. The vast majority of scientific evidence points to the fact that dramatic action is needed immediately if we are to maintain a good quality of human life for future generations. A 2019 Harvard University study indicated we have 5 years to take significant action, or it will be too late to slow the affects of climate change ([Vandette, 2019](#)).

The good news is that we can make positive change. It begins with education that this problem exists, the impacts, and what companies and individuals can do to reduce the impact. For consumers, this means combining trips to the store—or online shopping purchases to minimize their carbon impact. Choosing the slower shipping mode allows the retailer to combine your shipments even if it means waiting. It means buying items in person that are likely to be returned if you cannot see them or try them on. This will reduce the impacts of the returns process, which affects freight emissions as the item is picked up from a consumer's home and shipped to another location, then often shipped again to a distribution point where it may be reshipped to a consumer, a

store, or landfill. Clothing and shoes purchased online are returned about 30%–50% of the time, versus about 5% for in-store purchases. Consumers should think twice before hitting the purchase button for these types of buys.

Businesses can ship smarter and instill a low-carbon shipping culture into their company. Many of the techniques in **Table 5** will save money. This money can be reinvested in technology, bonuses for reaching GHG reduction targets, or more education.

Introduction

As a response to increased environmental and social challenges, new concepts and constructs have entered the logistics arena, such as the consideration of corporate social responsibility (CSR) and sustainability in supply chain management. What do these terms mean? This very much depends on whom you ask and when you ask, as the concepts may mean different things to different people at different times. In the 1980s and 1990s, when logistics managers referred to sustainability they often only meant the economic sustainability of the company. Logistics researchers in the late 1990s used the term “environment” solely for the business environment in terms of, for example, competitors and markets (and “green” for what is now more commonly referred to as the environment). In 1987, the United Nations-funded report “Our common future” proposed the still most-cited definition of sustainable development: “sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs” (Brundtland et al., 1987). Sustainability, therefore, comprises the three interdependent pillars of economy, environment, and society, commonly termed as the triple bottom line (3BL). Today, the United Nation’s Agenda for Sustainable Development 2030 presented in the year 2015 is commonly referred to when describing sustainability.

Commercial organizations, together with other stakeholders (e.g., politicians, consumers, and researchers), share the responsibility to work toward sustainable development. CSR can be described as a corporation’s way to address sustainability. CSR has developed from being a theoretical discussion about the role of business in society to become an integral part of logistics management and something seen as a business opportunity. Increasing recognition of CSR as a core business activity was also demonstrated by the launch of ISO 26000 in 2010. Thus, the traditional logistical mission of creating business/economic advantages is now starting to be replaced, or at least complemented, by a broader concept driven by social responsibility.

The Characteristics of CSR in Logistics and SCM

Despite the growing importance of CSR considerations in logistics and freight transport, there is still a lack of comprehensive approaches to the CSR construct in academic literature and organizational practice. Concepts such as logistics social responsibility and sustainable supply chain management are discussed by some (Carter and Jennings, 2002). Taken as a point of departure in the wide range of different definitions and descriptions of sustainable supply chain management, sustainable logistics, social responsible logistics, etc., a number of more commonly mentioned characteristics can be found. These are further elaborated on later.

CSR Covers a Myriad of Aspects

Sustainability for a corporation encompasses the consideration of its impact on the environment and society, while maintaining economic viability. The environment, society, and economy are the three sustainability dimensions. The 3BL, often referred to as “people, planet, and profit,” is a terminology commonly applied by corporations when describing their sustainability performance. However, when the CSR concept needs to be operationalized and sustainability plans put into action, it quickly becomes complex and a myriad of aspects and areas to consider arise.

One framework commonly used by corporations for accounting and reporting of their economic, environmental, and social performance is the Global Reporting Initiative (GRI) framework, developed by the GRI (Milne and Gray, 2013). The framework divides the three dimensions into close to 30 areas to report on, covering social aspects such as labor practices (e.g., employment, health and safety, labor/management relations, diversity, etc.), product responsibility (e.g., labeling and marketing communication), environmental (e.g., the use of energy, materials, and emissions), and economic aspects (such as income and market presence).

At the same time, one of the broadest and most universal policy agendas that world leaders have pledged common action on is the United Nation’s Agenda for Sustainable Development 2030 (United Nations, 2015). This agenda put forward 17 sustainable development goals (e.g., climate action, no poverty, zero hunger, gender equality, etc.) and 169 associated targets. However, most authors and practitioners within the field tend to focus on a selected sustainability area, for instance impact on climate change, air pollution, waste generation, diversity of workforce, safety records, etc. This is because the scope of CSR is so broad and complex that it is difficult for one single corporation or research study to cover it all. The development of CSR policies and the management, monitoring, measurement, and reporting of CSR performance are resource-intensive activities, and only selected companies are able to dedicate the time and money necessary to provide a holistic picture of their CSR involvement.

Three Interrelated and Interdependent Sustainability Dimensions

These three dimensions of sustainability are interrelated and interdependent, which means that synergies/win-wins, as well as trade-offs, exist between them. This emphasizes the importance of taking a holistic approach when analyzing the consequences of, for example, different logistics decisions. There could be trade-offs both within one dimension (e.g., individual vs. collective interests within the social dimension) and among the dimensions (Piecyk and Björklund, 2015a). The interdependence can also be described as “pop-up” effects that can arise from actions taken in order to eliminate or decrease a negative environmental or social impact. Addressing one problem (press down) makes new problems arise. One example is, as a response to the climate challenge, to change from traditional fossil fuels to batteries, raising new challenges such as the labor situation in the mining industry and the type of new unfamiliar substances/metals with unknown long-term health and/or environmental impact. Despite this, both researchers and practice commonly address one dimension or one aspect within a dimension separately and in isolation.

Environmental and social performance is sometimes described as an “add on” to traditional (economically focused) business practice: to carry on “business as usual,” but to add in the consideration of the impact on the environment and/or society. However, more and more researchers and practitioners are starting to have another approach toward this, presenting the sustainability work as an integrated part of their performance, thus something that cannot be separated from other activities or decisions. For example, is the person responsible for sustainability in a logistics firm seen as a resource for guidance or an important member of the company board? Can the purchasing manager order from suppliers not approved by the sustainability department or not? Some researchers within logistics might even go so far as to suggest the need for a more “eco/sociocentric” approach where all logistics decisions/changes are furthestmost taken on the basis of their social and/or environmental impact.

Benefits From Applying CSR in Logistics

Despite the fact that CSR derives from the altruistic desire to do good and act in a morally correct way, current thinking suggests that CSR initiatives can also generate competitive advantage for the firm (Porter and Kramer, 2006; Kucht Campos et al., 2018). Several studies have focused on the trade-offs between economic and environmental/social performance. Environmental and social actions have traditionally been associated with additional cost for the corporation. However, a paradigm shift has started to take place linking sustainability initiatives to improved economic performance and several of the more recent studies suggest that the link between CSR and a firm’s profitability is becoming closer. If undertaken in the correct manner, CSR initiatives can provide several corporate benefits such as: improved reputation; facilitating employee recruitment, commitment, and motivation; increased operational efficiency; improved relations with customers, suppliers, investors, and local society; improved risk management and a readiness for new legal demands/requirements; improved product quality and increased product value; a potential to target new markets and consumer groups; as well as knowledge development. CSR activities can thereby be vital to a company’s profitability, pointing at the critical role CSR can play with regard to a corporation’s overall strategy and success (Piecyk and Björklund, 2015b).

It is a challenge to understand the complexity and possible trade-offs in the specific situation. Initiatives might not influence the 3BL in a straightforward way, as these initiatives could strengthen company reputation and thereby indirectly increase sales, while simultaneously increasing manufacturing costs. Furthermore, the results are also dependent on the measurements and system limitations applied. Different results can be found, for example, if restricting economic performance to unit manufacturing cost compared to total costs or sales. Furthermore, these win-win situations seem to have as much to do with the type of actions taken as

the situation and specific context of the corporation taking these actions, as well as the classical “it is not about what you do, but how you do it.”

Closely related to the benefits of applying CSR are the reasons why companies engage in the CSR programs:

- Regulations—where sustainability actions are undertaken in order to comply with existing regulations (i.e., a passive/responsive approach). Proactive organizations may also develop strategies to comply with anticipated future regulatory changes (e.g., logistics operators investing in alternatively fueled vehicles in the expectation of potential carbon taxes or low emission zones, etc.).
- Reduced cost—where environmentally or socially sustainable behaviors can reduce the operating cost of an organization (such as avoiding payouts or reduced insurance premiums as a result of few employees involved in workplace accidents, reduced fuel bills as a result of energy saving programs), or help it to avoid penalties for noncompliance.
- Increased profits—a company can gain a competitive advantage from its sustainability-focused differentiation strategy and the development of new sustainable products or services. Improved corporate image and green marketing can attract new and existing customers who are willing to pay a premium for green and/or ethical offerings.

Organizational culture and top management support are key antecedents to successful CSR programs in organizations. Other factors include the regulatory environment within which a firm operates, stakeholder pressure, and the personal values and beliefs of managers and staff.

On a Voluntary Basis

CSR is commonly described as “a concept whereby companies decide voluntarily to contribute to a better society and cleaner environment” (CEC, 2001, p. 2). It is notable that CSR is commonly described as something corporations do voluntarily, as a response to, for example, ethical/moral and/or economic incentives. The sustainability responsibility of corporations has a basis in economic responsibility: thus, a responsibility to generate revenue for the owners and to provide products and services in a market economy (Carroll, 1979). This is followed by the legal responsibilities to obey laws and regulations. Climbing on the social responsibility ladder, or pyramid as commonly referred to, there are two more voluntary steps: ethical responsibility, to manage business in a fair and responsible way, and philanthropic responsibility, to contribute to the development of society.

Consideration of Numerous Stakeholders

To meet stakeholder sustainability requirements is the most important driver for companies to improve sustainability. This has also been singled out as an important driver within the logistics area. Stakeholders could be local communities, employees, investors, as well as members of the supply chain, including suppliers and customers. In particular, the social dimension involves a wide range of stakeholders with different goals, demands, and opinions.

Governmental regulations and increasingly strong market signals from environmentally and socially conscious consumers are also important drivers for CSR considerations in logistics practices. For example, research studies show that purchasing companies place a high value on the environmental performance of logistics service providers (LSPs).

Collaboration and Coordination

In response to shifting business climates (e.g., as experiences with globalization and an increased focus on core competences) and thereby growing supply chains, sustainability has expanded from the domain of individual companies to that of their supply chains. A product or service is never more sustainable than the weakest link in its supply chain. Corporations have started to recognize the need to address sustainability in a way that encompasses not only their own operations, but also those of other supply chain actors. This calls for greater consideration of sustainability not only within the focal company, but also encompassing the entire supply chain. Sustainable supply chains call for interorganizational interactions in order not to move sustainability problems between supply chain actors; practices performed in firm-internal isolation are also said to be less successful. The importance of collaboration and coordination between actors in the supply chain (described as, e.g., cooperation among companies along the supply chain to collaborate with its supply chain partners and collaboratively manage intra- and interorganization processes) are put forward in the descriptions of sustainable logistics/supply chain management. The interorganizational interactions necessary can range from strategic, based on collaboration and/or partnership, to more operational, arms-length and control-based forms. More close and strategic forms of interorganizational interaction is often put forward as necessary for the development toward sustainable supply chain management, described in terms of, for example, partnerships, mutual investments and adjustments, knowledge exchange, and standardization of/development of mutual goals and norms.

Long-Term Perspective

Sustainable development put forward “future generations” as its time perspective. This is far beyond the range of quarterly reports and even the strategic focus of corporations that seldom span beyond a 5–10-year time horizon. Even if several definitions of sustainable supply chain management use wordings such as “to improve in a long term perspective,” few (none) provide a clear

description of how long this could be. Selected time frames when calculating, for example, a return on investment, can decide if an investment in a more environmental or social logistics solution is economically beneficial or not.

An Add-On or an Integrated Part

Some definitions/researchers describe sustainability as an aspect that could be added to traditional approaches to logistics management and decisions with regard to the design of logistics systems. Thus, adding sustainability to the agenda, while keep on working more or less the same way as traditionally. One example is where the sustainability actions are not influencing normal practice, but instead could be seen as adding additional KPIs or taking actions that do not result in changes in the way the logistics system is managed, such as donating unsold product to charity or using more modern and less polluting trucks.

Another approach to sustainability within logistics and supply chain management involves viewing it as an integrated element of logistics management. Thus, sustainability performance should not be seen in isolation, but instead as something that influences the traditional way of managing logistics systems. One example is if the top management decides that all suppliers must be approved by the sustainability department. Another example is if it is decided that sea transport should be used to a larger extent for transporting the company's goods. These types of actions also influence the management of other parts of the logistics system redefining, for example, the potential supplier basis or the time management of the logistics flow.

Corporate Social Responsibility in Logistics Activities

Approaches and responses to logistics sustainability pressures will vary depending on the type of organization. A manufacturing company with a mainly outsourced logistics function will engage in the sustainability agenda in a different way than a manufacturer with in-house logistics operations, a retailer, or an LSP. As the core value-adding activities will vary among these organizations, so will the magnitude and nature of their environmental, social, and economic impacts and thus their CSR agendas. The size of an organization will also determine the range and the level of sophistication of its sustainability initiatives (Piecyk and Björklund, 2015a). This may be due to the available resources, workforce knowledge and skills, legislative and regulatory pressures, and external support offered to the company in question. The experience or CSR maturity of a company will also play an important role in developing and implementing sustainability programs. Organizations that are only just starting on the CSR journey might focus more on output-oriented actions, such as a change of technology to achieve an instant drop in greenhouse gas (GHG) emissions. More mature organizations are more likely to engage in a broader scope of initiatives, often with a more strategic focus. Actions implemented may be more closely related to the redesign of processes, organization, management, etc., that is, a focus on improving the ways of working, rather than immediate results. These types of initiatives tend to produce consistent but slow-paced gains in the future, rather than quick wins often desired by new CSR players willing to quickly demonstrate their dedication to the cause.

This section takes its point of departure in three central logistics activities (purchasing, warehousing, and freight transport), and elaborates on how different aspects of sustainability can be addressed within these activities.

Purchasing

Purchasing social responsibility (PSR) can be defined as the inclusion of CSR issues advocated by a company's stakeholders in purchasing decisions. The purchasing function can be viewed as a key mechanism an organization can use to extend its CSR standards to suppliers, sub-suppliers, and contractors, thus improving the social and/or environmental performance of the whole supply chain.

The key environmental practices in PSR are related to purchasing goods with better environmental credentials, using environmentally sound suppliers, cooperating with suppliers to ensure their processes are environmentally sustainable, participating in the design of products and packaging for reuse or recycling, with the aim of minimizing the use of energy and materials at the production, and using an end-of-life stages in the product life cycle. Other actions include sharing cost, risk, and responsibility for investments in new technologies in places where they can generate the most difference, that is, usually the poorer countries where manufacturing operations take place but the cost of new technologies is prohibitive for local companies.

With respect to the social aspects of PSR, managers should ensure that fair and transparent protocols are followed in the purchasing process, whereby the offer and any confidential information obtained from a supplier is not shared with their competitors in order to obtain better quotes, contracts do not use unclear or misleading terms to gain advantage over suppliers, and common terms are stated in, for example, codes of conduct that are signed by the focal firm and its suppliers. Not accepting bribes, gifts, meals, etc., from potential suppliers are also key components of purchasing ethics. Staff involved in the purchasing process should be made aware that potential suppliers should be offered an equal playing field independent of personal preferences, likes and dislikes, gender, political affiliations, religious beliefs, or ethnic status.

While managers have full control over the internal processes, due to progressing globalization and a trend toward the outsourcing of noncore activities, over the last decades supply networks have become increasingly complex, often involving multiple tiers of sub-suppliers located in different countries. It is, therefore, very challenging but crucial for businesses to monitor the human rights performance of their suppliers in order to avoid forced, sweatshop, or child labor, and ensure that their suppliers pay living wages

and ensure safe working conditions for their employees. More proactive companies may get directly involved in educating workers with respect to their rights at suppliers' premises. Collaborations with third party organizations such as, for example, the Better Cotton Initiative are also a way to ensure sustainable supply sources in global supply chain networks.

Unfortunately, while the purchasing function is a powerful tool to ensure that a company's sustainability principles penetrate deeply into the supply chain, it is also sometimes used to simply transfer the efforts and investments required to make the product or service more sustainable to the least powerful partner in the chain. While purchasing from a greener supplier is often an important first step for companies starting on the environmental sustainability agenda, as their experience, knowledge, and skills develop, attention should be shifted to internal efforts to improve their own operations and strengthening external links to actively participate in the joint development of greener products or services.

As the trend toward the outsourcing of logistics services continues to grow in importance, companies increasingly incorporate CSR-related requirements into their purchasing process. As a result, demonstrating dedication to environmentally and socially responsible ways of operating becomes a significant differentiation factor for LSPs. The subsections later present an overview of key CSR considerations in freight transport and warehousing.

Freight Transport

Companies often tend to focus their CSR considerations in relation to freight transport on the environmental aspects of sustainability. As moving cargo is a significant source of anthropogenic GHG emissions and air pollutants including nitrogen oxides, sulfur oxides, and particulate matter, these are often reported and acted upon as key performance areas. This prioritization is also based on the green-gold approach, where actions aimed at reducing energy use and resulting emissions also result in lower operating costs. Mode-specific environmental impacts are also important: for example, vessel discharges and invasive species transfer for shipping, noise for airfreight, or chemicals used for weed control on tracks in the case of rail freight operators.

In terms of the social aspects of CSR, the emphasis is usually put on the safety aspects. The CSR actions focus on continuous vehicle operator training, drug and alcohol testing, appropriate equipment maintenance, abiding by hours of service, and weight restrictions requirements. Also, logistics is a very male-dominated industry. The need for some physical strength, time spent away from home, and not well equipped and potentially unsafe "resting places" could partially explain the reasons for that. Actions to improve the gender balance and diversity of the workforce are important social aspects of CSR agendas. Quality of life for long-distance drivers is a vital CSR concern in logistics, particularly if the type of operation requires frequent and lengthy periods away from home. Paying adequate wages and the diversity of workforce are also commonly mentioned as important social issues companies need to address. Human rights, for instance complying with child labor laws, also need attention from companies involved in freight transport, especially where the supply chain involves operations in less developed countries with regulatory regimes that leave poorer members of society vulnerable to the danger of exploitation and human rights abuse.

The sustainability of last-mile transport operations has recently attracted significant attention. From availability and fair pricing of deliveries to far-flung places, to the contribution to congestion in densely populated urban areas, there is a whole range of sustainability impacts that should be considered with reference to the final leg in the distribution chain. A significant social sustainability issue related to the last-mile delivery that has been attracting perhaps most attention in recent years relates to the emergence of the so-called gig economy. By the gig economy, we mean a system in which, rather than using own staff on traditional employment contracts, companies use short-term contracts with independent, self-employed workers to carry out the work. Such practices significantly cut costs for the organizations in question. However, while some workers enjoy the flexibility of their self-employed status, there is a growing concern about the lack of employment and income protection for those on zero-hours contracts and the long-term social consequences (e.g., the lack of workplace pension support) of such practices.

Autonomous freight vehicles, currently being tested in a number of countries around the world, may also have some significant CSR consequences in the freight transport sector. On one hand, they are likely to alleviate the economic pressures many companies currently face as a result of increasing driver shortages. On the other hand, at least in the short term, they may exaggerate the problem, as young people are less likely to invest in the training necessary to enter the profession (e.g., an HGV license) knowing the jobs may not even exist anymore in 10 years time.

Warehousing and Terminals

Logistics sustainability initiatives should also be incorporated into the warehouse, distribution center, terminal or logistics hub design, and operation. The first key decision in design for sustainability is the number, location, and capacity of distribution facilities, as this will largely determine the transport intensity of the overall logistics network. The decisions taken at this stage will have consequences for transport distances, potential to use more efficient equipment, access to terminals and opportunities to use less energy-intensive transport modes, as well as the ability to consolidate transport flows for a better utilization of transport resources. Locating distribution facilities in the proximity of environmentally sensitive areas may have profound impacts on biodiversity and/or soil quality (e.g., due to leaks or spills). 24/7 operations are increasingly common in the distribution industry and this too may have a detrimental effect on nearby residential areas, with noise and visual intrusion being of particular concern to local communities.

In warehousing there is a strong focus on the social aspects of CSR, with particular attention dedicated to measures aimed at improving workers' safety and accident prevention. Typical actions include training provided to staff to increase the safety of

handling equipment use, maintenance of a clean, safe, and healthy work environment, and the ability to quickly respond to any accidents in order to save lives and to minimize damage and disruptions. Policies to ensure workforce diversity, equal pay, and ensuring the availability of healthy meal options in workplace eateries are also keys to socially responsible warehouse operation. Another key dimension of social responsibility is paying warehouse workers living wages rather than minimum wages. A living wage can be defined as the minimum income that allows a worker to meet their basic needs without relying on extra support from the state. It is usually higher than the minimum wage, that is, the lowest wage an employer can legally pay their staff.

Environmental aspects of warehouse operation focus on reductions of energy use in lighting, temperature control and handling equipment use, prevention of refrigerants leakage and associated GHG emissions, as well as proper storage, labeling, and packaging of hazardous materials. Appropriate inventory management is also important to prevent economic and environmental losses associated with the obsolescence of stock, and so are policies to maximize the level of reuse and recycling of packaging material and the safe disposal of waste.

Actions to prevent theft and shrinkage are important for the economic sustainability of warehouse operations. Careful inventory management to prevent product obsolescence is another example of economically sustainable action in a warehouse. By tight control of stock rotation, companies can not only improve their profitability, but also reduce the risk of products going out-of-date and being wasted, thus also improving their environmental results.

From Sustainable Logistics Toward Logistics for Sustainability

Traditionally, the key objective of logistics as a core business function was to contribute to gaining and maintaining the competitive advantage of a company or a supply chain, by maximizing the level of customer service while simultaneously minimizing the cost of delivering that service. The focus was purely on profit generation, that is, ensuring the economic sustainability of a business. As the concept of sustainable development has risen to the top of political and corporate agendas, social and environmental concerns put constraints on untamed economic development in order to prevent social exploitation and ensure that enough natural capital is preserved to meet the needs of future generations.

However, what is the future role of logistics systems? The perception and understanding of logistics ought to look beyond its traditional business function, and focus on the true social values that well-functioning and sustainable logistics systems bring to modern economies. Logistics in itself is a core to a sustainable society.

First of all, without logistics there would be no modern societies. Without everyday transport of chemicals for water treatment/purification plants, we would not have clean water in our homes. Without transport links, housing areas would be dependent on the proximity of food supply. Waste and sewage removal is a highly complex logistics operation. Modern cities only exist thanks to highly complex, efficient networks ensuring that the goods and services we consume in everyday life are delivered at the right time and at the right cost to the place where they are needed.

Recently, increasing attention is given to the development of the logistics systems that are created with the aim of contributing to a better environment and/or society. Examples of such systems include:

- Humanitarian logistics, for example, the design, management, and operation of a logistics system, developed to support people in need due to, for example, natural disasters by providing them with emergency or continuous supplies of food, shelter, or equipment needed to alleviate poverty.
- Food banks and the redistribution of surplus food from private homes, supermarkets, food producers and retailers, cafes, and restaurants to people in need. Apart from formal initiatives introduced, for instance, by retailers as part of their CSR programs, the widespread reach of social media facilitates the development of less formal civil society networks that want to do good by sharing functional food that otherwise would go to waste.
- Secondhand, freecycle, and upcycle networks where people sell or give away unwanted items in order to reduce waste and support other members of society.
- City logistics initiatives spurred from the will to improve the quality of life in densely populated urban areas. In order to combat the increased level of noise, congestion, and pollution, various initiatives aiming, for example, to consolidate transport, use greener vehicles, or introduce off-peak deliveries are initiated.

The aforementioned logistics systems are designed primarily with nonfinancial objectives in mind (i.e., the urge to do right, to help people in need, to improve societies, and/or to decrease the environmental impact) that take priority over the traditional criteria of profit and competitiveness. Ad hoc distribution activities, planned and carried out by non-logisticians, and a short required response time, often mean that the nature of transport movements is inefficient. For instance, leftover food from restaurants is redistributed in poorly utilized passenger cars. As a result, the positive social impact might come at the price of increased environmental pollution. While the negative environmental impact of logistics activities is often an obvious sacrifice to make in order to alleviate the suffering of vulnerable people (e.g., when airfreight is used in humanitarian logistics to reach people affected by a natural disaster as quickly as possible), in the longer term the lack of economic, environmental, and social balance in logistics activities may put the whole initiative in jeopardy. Evidence shows that several well-intended sustainability initiatives in city or humanitarian logistics, for example, have been abandoned due to the inadequate economic performance or lack of basic logistics skills and knowledge. Logistics systems, even when designed with a grand sustainability objective in mind, need to be economically viable to survive and a healthy profit provides a basis for further development and upscaling potential. The highly skilled, well-

trained, flexible, and resilient logistics managers of the future are needed not only in businesses, but also in municipalities, hospitals, and nonprofit organizations such as charitable or humanitarian agencies.

The way we see logistics and the knowledge researchers develop within the field is constantly evolving in response to demographic and social pressures, the changing nature of the demand and the type of logistics services required, advances in data collection and processing, and social media and communication protocols. However, as environmental and social sustainability are definitely going to stay at the top of the social and political agendas, more and more attention needs to be given to CSR considerations in logistics and supply chain management operations.

Biographies

Maria Björklund is an Associate Professor of Logistics Management at the Department of Management and Engineering, Linköping University, Sweden. She received her PhD within the area of green logistics in 2005 from Lund University, Sweden. She researches, publishes, and lectures within the fields of sustainable supply chain management and logistics, with a focus on environmental and social considerations in logistics and purchasing, city logistics, logistics for sustainability, sustainable logistics-based business models, interorganizational interaction for sustainability, and green performance measurement. She is currently leading two research projects financed by the Swedish Energy Agency and the Kamprad family foundation for Entrepreneurship, Research & Charity.

Maja Piecyk-Ouellet is a Reader in Logistics at the University of Westminster. She is a former Deputy Director of the Centre for Sustainable Road Freight, an EPSRC-funded research center between Westminster, Heriot-Watt, and Cambridge Universities. Her research interests focus on the environmental performance and sustainability of freight transport operations. Much of her current work centers on city logistics, CSR, GHG auditing of businesses, and the forecasting of long-term trends in energy demand and environmental impacts of logistics. She is a Fellow of the Higher Education Academy. She is currently leading the University of Westminster’s input to the EPSRC-funded Freight Traffic Control 2050 project (EP/N02222X/1), the Volvo Centre of Excellence in Sustainable Urban Freight Systems (CoE-SUFS) and is carrying out research for the Centre for Sustainable Road Freight.

Introduction

In recent years, many global businesses have been involved in collaboration to improve overall performance through collaborative mandates. The initiatives of Walmart in collaborative planning forecasting and replenishment (CPFR) have attracted many businesses around the globe. Subsequently, several retailers and manufacturers, such as Procter and Gamble, Sara Lee, Nabisco, etc., have adopted CPFR (Ireland and Crum, 2005; Seifert, 2003). However, there is still no clear evidence on the benefits of collaboration, information exchange, or business analytics for the participating companies in specific contexts. One of the main reasons behind this ambiguity is the paucity of case studies documenting experiences and success stories.

Supply chain research on information exchange (Barbosa et al., 2018) focuses mainly on two areas. One is production and replenishment, and the other is forecasting and planning. Either cost reduction or inventory control is the primary motive of these supply chain collaborations. Initially at the inception of CPFR, an understanding of the collaboration process and the framework to collaborate were considered the two basic requirements for a collaborative supply chain. At a later stage, information sharing was recognized as one of the key elements of success for collaborative relationships (Ramanathan, 2012) and it was asserted that the benefit of information sharing is dependent on two factors: one is content and the other is proper use of information. Distorted information and inefficient use of available data will lead to excess inventory in each level of the supply chain. Hence, it may be important for the companies under collaboration to decide on what information is to share to reduce the cost of logistics and inventory, to create more accurate demand forecasts, to make production flexible, and to achieve timely replenishments.

In the 21st century, information in collaborative supply chains is being used to make joint business decisions. Business analytics involving in-depth data analysis are becoming integral parts of leading businesses in order to plan production and distribution. In recent times, particularly after the introduction of 3G and 4G technology, many logistical services namely DHL, FedEx, Amazon, Ocado, and many others around the globe are connected with warehouses, production plants, and service centers for inventory data, order data production, completion schedules, delivery schedule plan, etc. This connection is made available through technology, such as Internet of Things (IoT) sensors, Radio Frequency Identifications (RFID), bar codes, social media platforms, cloud computing, and Big data analysis.

From the literature, it is evident that the importance of sharing demand information with all supply chain members (both upstream and downstream) can help reduce the manufacturer's supply chain cost, specifically reducing the inventory costs of both supplier and customer (Ramanathan, 2012). The manufacturer could reduce the variance in demand forecast, if readily available historical order data and current demand data are used efficiently for decision-making. Walmart has set an example for retailers to practice transparent information sharing. Especially, the sharing of demand information with manufacturers or suppliers has been widely encouraged by Walmart under CPFR adoption in the USA. Point of sale (POS) data and market-data were found influential in achieving forecast accuracy in the "augmented CPFR" model (Chang et al., 2007). Recognizing the type of information to be shared among supply chain members to build visibility is a big challenge in achieving collaboration. In some businesses, under high demand variability, long-term forecasts performed better than short-term forecasts. Under low demand variability, short-term forecasts performed better than long-term forecasts. Previous research using store level stock keeping unit (SKU) data, found that simple time series forecasting will be appropriate for normal sales without promotions, but we need advanced techniques to improve forecast accuracy of promotional sales and logistical planning. Several examples on the benefits of sharing supply chain information and business analytics in managerial decision-making have been reported in professional journals and magazines, such as Focus from CILT and Professional Manager from CMI.

The main objective of this chapter is to discuss the role of supply chain information and business analytics in collaborative logistics planning, inventory management, and distribution. The rest of this chapter is organized as follows: Section, "Collaboration for Supply Chains and Logistics" describes collaboration among supply chain partners both upstream and downstream with respect

to the role of information sharing, business analytics, order generation and replenishment. This section also touches upon sustainability aspects in logistical collaborations. Section, “Conclusions” concludes with possible future research notes.

Collaboration for Supply Chains and Logistics

Role of Information and Business Analytics

While we appreciate the role of data analytics in business decision-making process, we also understand some negative effects of business analytics on the decision making of leading companies. For example, Tesco has used customer data extensively by means of their customized software and has used club card data for customer analysis to distribute gift coupons and discount vouchers. This attracted many customers for nearly half a decade and then this promotional approach slowly lost its power of retaining loyal customers. This sheds a light on the decision making of leading companies who used the power of data; conquering the competition with data analysis may not be successful for companies if they compromise collaborative decision-making and innovations.

In a collaborative framework such as CPFR, the point of sale (POS) information among organization is flowing mainly to forecast the demand. All partners will normally discuss various factors behind the sales figures, especially peaks and dips. This will help them to arrive at a single collaborative forecast figure that will be used to plan and control the production, warehousing, and inventory in line with the sales data, preferably the POS data. In Vendor Managed Inventory, solely suppliers will carry out the same exercise (Barratt and Oliveira, 2001). However, today’s competitive world requires better data storage and management in order to use business analytics to ensure a comprehensive business solution. Real time data analysis and business intelligence are an integral part of businesses to fulfill logistical requirements to gain customer satisfaction while fighting to survive the competition (Fig. 1).

In collaborative supply chains, all players will come forward to see the usefulness of the available information through multi-level discussions and formal agreements. For example, what information is required to maintain service level, inventory, production planning, and demand? Can in-depth data analysis lead to operational planning and forecasting? Will further managerial decision-making based on the analysis inform the business to improve their services? These details will help the businesses to decide the level of collaboration among partners for various purposes such as warehouse management, logistical services, and distribution planning (Ramanathan, 2011). The CPFR framework supports part of these processes, namely collaborative planning, forecasting, and replenishment, by sharing demand information from downstream partners. Fig. 1 represents the current business process enhancements in the presence of collaborative information exchange and the introduction of Business Analytics. This approach helps to inform collaborative decisions in fast moving supply chains. Global businesses such as Amazon and Alibaba manage their logistics, services (both delivery and warehouses) effectively through business analytics. Table 1 provides a list of important business analytics capabilities for modern logistics operations as compiled by the 2019 3PL Logistics study (3PL Study, 2019) (Table 1).

The inclusion of block chain in the list is an interesting addition to logistical capabilities and a true reflection of the inclusion of technology innovation in logistics. It has been reported that the IoT sensors, along with block chain capabilities, have the potential to revolutionize the way logistics firms operate (Porter and Heppelmann, 2014). For example, smart roads (using IoT sensors) and specially devised SatNavs with information on road quality, fuel efficiency, and local traffic are fitted in many trucks in the UK and Europe to make a quick decision on routes, considering the live traffic situation. The capabilities of IoT sensors and block chain technology are further enhanced using artificial intelligence techniques (e.g., smart contracts) and other decision support tools.

Level of Collaboration Among Supply Chain Partners

In order to have a higher level of support from supply chain partners, one of the essential factors is establishing a close relationship with partners. In the literature, it is argued that not all supply chain partners will have same level of collaboration (Ramanathan, 2011). Companies operating under high competition will need to have open information sharing and strong collaborative relationships with trusted allies in order to thrive and succeed. This is named as “Futuristic Collaboration.” The other two levels of collaboration namely “progressive collaboration” and “preparatory collaboration” are suggested by Ramanathan (2011). Here,

Figure 1 Role of collaborative information in supply chain logistics and distribution.

**Figure 2** Order generation—traditional approach.

the choice as to the level of collaboration is highly dependent on type of business and partner requirements. For example, functional products with no fluctuation in their demand patterns will have a basic preparatory level of collaboration. However, in businesses with high variability in customers' demands due to the fast moving nature of the product, the level of collaboration needs to be intense, such as futuristic collaboration. This will allow companies to have open and transparent information exchange. The level of collaboration and order generations are closely related to each other (Baratt and Olivera, 2001; Ireland and Crum, 2005). For example, a vendor managed inventory (VMI) approach will make ordering straightforward with vendors in place and a CPFR will manage automated orders. However, "no collaboration" or "no information" will trigger orders only when the buyer is making efforts to place orders either through historic sales figures or on checking the inventory level. Fig. 2 represents the order generation in traditional supply chains. Here historic sales data was in use to make production, inventory, and replenishment plans. This required very basic collaboration such as "preparatory level" collaboration (Fig. 2).

In contrast, Fig. 3 represents supply chains of the 21st century in the presence of live data. Global businesses normally value all customers and attempt to serve them to the highest possible level. As the market becomes demand driven, the companies need to go for business analytics to see customers' preferences and market trends in order to survive the competition. This requires the involvement of live data in planning, forecasting, delivery, and decision-making; hence, business analytics has become a new norm for businesses (Fig. 3).

Many global companies that operate from various countries, such as DHL, FedEx and Amazon, have a wide range of customers from big national chain customers, such as Tesco, to small local shops and convenience stores. It is crucial to maintain a close and healthy relationship with all these customers. From the inception of the internet, the companies around the globe are using a variety of Windows-based solutions such as an "EPOS ordering system" or something similar to Walmart's "retail-link" to communicate with business and supply chain partners. This new system assists retailers to benefit from a full product file, pre-installed system, so that orders can be placed electronically to the suppliers, and encourages their customers to use Windows-based systems by valuing customers' participation in profit earning and timely replenishment.

Figure 3 Replenishment using live data and business analytics.

The Ordering Pattern—Traditional Approach

Some companies still follow order generation through the “traditional method,” which is based on their respective order from the customers (Fig. 2). In order to avoid stock-outs, some companies maintain 5 days of safety stock for functional products, such as coffees and beverages. Initially, demand analysts make their order forecasts by looking at historic sales data and adjusting this based upon order input from the retailers. Based on order forecasts and current inventory levels, retailers, or wholesalers place orders to suppliers. On receiving orders from downstream partners, the supplier plans its replenishment. This process usually takes place for a total of 3 days, where Day 1–Day 3 delivery signifies that:

- Day 1—placing order, deciding site from where order has to be replenished and deciding plan for dispatch.
- Day 2—moving necessary stock in between the warehouses to gain cost benefits.
- Day 3—delivery of order.

This ensures timely replenishment at retail outlets, as long as the outlets are located within 100 miles. The above stated procedure adopted by the supplier for order generation is a simple and straightforward method, but does not consider potential complications. The sales team of the company will normally use historic sales data to place orders with suppliers. Orders from retailers and inventory status are incorporated in the process of order generation. The supplier replenishes orders in 3 days. Some of the existing traditional operational problems can potentially be improved on the back of the mutual understanding of partners and on streamlining the current system using data analytics and collaborative decision-making.

Environmental Sustainability and Logistical Constraints

Some global companies have started encouraging bulk orders of one full truckload in order to maintain sustainability objectives. This quantity discount on bulk orders is hoping to provide customers with some extra time to order-up-to fill level. Obviously, customers need to wait to order until their order comes closer to the fill level of one truckload, if the company wants to enjoy a quantity discount. Initially, this approach has complicated the global company’s delivery to their customers; slowly, the companies have started learning how to make a profit on ordering a full container or full truckload.

In the case of ordering less than a full container or full truckload, companies try the other option of using its own vehicles to obtain delivery from the supplier. Some other companies with no investment capability have also started using 3PLs. A few companies have experimented with multipurpose/multi compartmental vehicles carrying a variety of products. Unfortunately, this has not proved successful as these vehicles have fixed space and hence it is difficult to accommodate unplanned products and deliveries. Later this idea was dropped in the international market due to its operational difficulties.

The introduction of online sales has added some extra logistical issues for retailers and for producers around the globe. However, e-tailing has shown its success in a variety of ways by increased customer satisfaction through logistical and service excellence despite the difficulties.

Any broken link in the supply chain increases lead-time and service performance. However, it can be concluded that the sharing of demand forecasts with suppliers will reduce uncertainty and, hence, could improve inventory positions. Information sharing and collaboration for data analytics has proved to have led to a higher level of precision in decision-making, as shown in the case of Walmart.

Conclusions

This chapter has highlighted, with some practical examples, how the power of business analytics can be combined with transparent information sharing in collaborative supply chains. If this study is extended for many global companies operating in different industrial sectors, such as pharmaceuticals, automobiles etc., a general opinion on the type of information and Business analytics can be suggested. It will also be beneficial to look at other possibilities for information exchange among wholesale companies and upstream partners.

Introduction

Logistics information systems deal with monitoring and control of information flows, material flows, and financial transaction-related flows within companies and supply chains. The purpose of the logistics information systems is to provide decision-making support, automated transactions, and data storage services for organizations to deliver the right quantities of goods at the right place and right time (Helo and Szekely, 2005).

Information systems in business logistics are gaining increasing importance as competitive advantage of supply chains is very often based on reliable, fast-response operations. Handling material flows within and between companies takes place across several functions, for example, (1) intra-logistics: procurement, production, shipping, and inventory handling functions, and (2) logistics occurring within the network: transportation, e-business, and supply chains.

Logistics information systems very often consist of various independent, but interconnected, information systems (Fig. 1). A central system for any company is enterprise resource planning (ERP) software that keeps records of the key business and material handling transactions of the company in a central location. Advanced planning and scheduling (APS) software packages operate on a network level that often consists of several enterprises and aims to optimize supply chain operations. Warehouse management systems (WMS) are handling information at the warehouse level and are often connected to operational automation systems. Transport management systems (TMS) are used for the planning and control of transportation events, route planning, and scheduling. Tracking and tracing software systems provide a real-time or close to real-time visibility for supply chain actors, in order to answer the questions of the origin of the items and where these are currently located. Business intelligence and big data analytics are bespoke systems built to collect information from various sources and to provide up-to-date performance indicators for each part of the operations (Addo-Tenkorang and Helo, 2016).

Enterprise Planning Systems

ERP systems have evolved from material requirements planning software to cover the entire integrated operations of business transactions in the company, including purchasing orders, sales orders, production planning, inventory management, finance, and human resources. ERP systems are based on a centralized database and client server architecture, which allows users to access current information in real-time (Kurbel, 2016). This integrated and centralized approach helps companies to handle automated processes between functions. For example, automated purchase handling can generate purchase orders for a vendor based on inventory level and triggering rules; goods received can be linked to purchase order number and the stock updated at the same time approving payment to the vendor.

ERP software functionality could include the following areas:

- Sales and distribution: offers, orders, pricing.
- Purchasing: quotations, vendor management, purchase orders.
- Production: production planning, master production scheduling, forecasting, material requirements planning, bill of materials, capacity management, quality control.
- Financial accounting: cost accounting, general ledgers, cash management, invoicing.
- Warehousing: goods receiving, shipping.
- Human resources: payroll, training records, recruiting.
- Project management: cost management, scheduling.

Figure 1 Logistics information systems in planning hierarchy.

Figure 2 Enterprise resource planning (ERP) system functionality is linked with business processes.

These functionalities are interconnected and provide the master data for important logistics transactions—including product data, customers, vendors, warehouse data—that is stored in a single up-to-date location available for different needs (Fig. 2).

Many ERP systems are based on industry best practices and standardized configurable business processes. Despite the differences, ERP systems share similarities as to how software modules are organized and how processes are built. Fig. 3 is a screenshot capture of Odoo ERP, an open source software. This figure shows possible applications (modules) available for the use of organizations.

SAP, Microsoft, and Oracle are some of the leading software ERP providers, but a great share of the ERP market is controlled by several smaller national vendors, which have industry-specific solutions or good local support for localized needs. Currently, ERP solutions are moving from on-premises hosted solutions to new cloud-based systems. This allows the building of better connectivity in supply chains. Typical use cases are portal solutions for the customers and vendors. Extending the scope of ERP beyond the enterprise is one of the leading themes in this area.

Transport Management Systems

TMS maintain an efficient delivery of materials from source to destination. The primary purpose of TMS is to schedule and optimize the transportation routes, track the fleet in real-time, minimize the transportation cost and delays, and improve logistics reliability (Barreto et al., 2017).

TMS is a component of supply chain management (SCM) that enables collaboration with an order management system (OSM) and distribution center (DC) or warehouse. Companies of all sizes have been employing TMS, particularly following the recent development and growth in TMS, to handle the high freight cost, coordinate with other supply chain technologies such as WMS and Global Trade Management System and to manage the electronic communication with customers, trade partners, and carriers (Barreto et al., 2017).

TMS take care of the daily planning and execution of transportation tasks. The TMS system typically received orders from an ERP system and is integrated with WMS as well. The functions of a TMS system are often tied with certain types of freight modes and can include the following capabilities:

- Transportation vendor management
- Freight invoicing

Figure 3 Odoo ERP application menu.

- Route planning
- Load and unload planning
- Asset management of vehicles, trailers, and containers
- Yard management systems
- Cost control and reporting
- Transportation tracking
- Quality management and transportation claims processing

A TMS system enables companies to accurately locate their fleets while in operation through GPS technology, oversee freight movements, negotiate with carriers, consolidate freights, and collaborate with intelligent transportation systems (ITS). On the planning side, TMS systems often combine a geographical information system (GIS) with an optimization system such as vehicle routing problem solvers which determine the daily planning based on cost minimization or according to a similar system-wide objective (Braekers et al., 2016). Fig. 4 illustrates Open Door Logistics, an open source software used to plan daily delivery routes and schedules. The optimization algorithm provides a solution for the relatively complex problem in less than a minute.

The Internet of Things (IoT) and TMS play a critical role in the transportation and logistics industries. Since more and more physical objects are equipped with sensors, barcodes and RFID tags, logistics companies can perform real-time monitoring of physical objects from an origin to a destination throughout the entire supply chain. On the other hand, vehicles are empowered these days with sensing, networking, communication, and data processing competencies, and IoT technologies can be utilized to improve logistics operations and fleet utilization (Atzori et al., 2010).

TMS are important sources of competitive advantage for companies operating in transportation. Large logistics companies such as DHL and FedEx have invested a lot of resources to optimize their transportation network by using advanced planning systems (APS) that aim to improve capacity utilization, minimize total costs, and reduce emissions. Industry-specific solutions have been built for air-based logistics (Feng et al., 2015), for maritime logistics (Helo et al., 2018), as well as for road transportation (Dibbelt et al., 2017). The possibilities to use various optimization algorithms have been increased as cloud-based solutions enables low-cost computing. The interest in autonomous vehicles and drones (Wang et al., 2017) is expected to drive this sector with artificial intelligence-related investments.

Warehouse Management Systems

A WMS is a database-driven computer application to enhance warehouse efficiency and retain accurate inventory through the recording of warehouse transactions (Ramaa et al., 2012). WMS are employed by various companies to obtain transportation and production economies, fulfill changing market conditions and uncertainties, achieve the minimum logistics cost corresponding to the desired level of customer service, and offer a combination of products instead of a single product per order.

Figure 4 Open Door Logistics software used for daily vehicle route planning.

WMS are software solutions used to conduct warehouse and distribution-related planning and execution tasks. These systems are often linked to certain types of warehousing system and increasingly linked with automation. The systems take care of planning, resourcing, and managing tasks to receive, move, and ship materials to and from warehouses. The controlled tasks can include:

- Goods receiving
- Order picking
- Packing
- Goods issue and dispatch
- Inventory management, storage locations, detailed stock keeping units (SKU)

In addition, a WMS can determine a temporary storage for disposable or recyclable materials, provide an intermediary location for transshipments, and maintain the just-in-time programs of suppliers and customers. WMS are a crucial component of a company's logistics system and contains four procedures: receiving products, storing the materials until they are requested, picking products from inventory, and shipping the products in response to customer orders. The order picking process is the primary function of a warehouse management system and lies at the interface between production and distribution systems. Order picking policy comprises basic order picking, zone picking, batch picking, and wave picking. In a basic order picking policy, pickers conduct a tour through the warehouse to collect all SKUs for a single order, while under a zone picking policy, a warehouse is divided into zones and pickers gather SKUs from a single zone. In batch picking, an order picker is restricted to a specific zone of a warehouse and simultaneously collects orders in order to reduce the mean trip time per pick. However, orders need to be sorted subsequently. In wave picking compared to zone picking, several workers pick different items of the same order at the same time from all zones.

The possible automation systems are often built around standardized material handling units, for example, plastic crates or pallets. The system layout and configuration may be a combination of the following automation building blocks:

- Automatic storage and retrieval systems (AS/RS), high-bay warehouses
- Conveyor belt-based systems
- Pick-to-light, voice picking, or other computer-guided human-based warehouse system
- Automated-guided vehicles (AGV)
- Robotic bin-picking systems (Huang et al., 2015)

Fig. 5 illustrates a screenshot capture of Open WMS systems example layout, which combines a conveyor belt-based automation system with multiple aisle collection points and manual operations. In this example, the WMS controls the procedures and guides each station operator.

The order picking systems are classified based on utilizing humans or automated machines to three system types, picker-to-parts, parts-to-picker, and a put system. In the picker-to-parts systems, which is the most common method in order picking, order pickers

Figure 5 Open WMS user layout with conveyor belts and collection points.

collect the items by walking or driving through the aisles. The parts-to-picker system employs AS/RS, which is majorly aisle-bound cranes retrieving one or more orders and delivering them to the pick location. The put system comprises both retrieval and distribution processes, where items are collected according to a parts-to-picker or picker-to-parts type in the retrieval process of the put system. An order picker afterward dispenses the carrier with the pre-picked items over customer orders.

Large logistics operators have invested a lot in advanced warehouse automation. Companies such as Amazon, which acquired Kiva Robots, and Alibaba are well-known examples of supply chain operators who are driving the technological developments (Li and Liu, 2016). Efficient and flexible automation is expected to deliver value for the entire supply chain.

Tracking and Tracing Systems

The identification, real-time tracking, and traceability of materials in supply chains have all been a demanding challenge for companies. Constant monitoring and handling rising shipment chains is vital in complex supply chains and logistics management. Various tracking and tracing solutions have been introduced to visualize where products are (tracking) and where they are originating (tracing).

In their simplest form, tracking systems are based on identification systems such as bar codes and processes supporting reading transactions into a centralized database. RFID is technology that has improved the automatic identification and data capture (AIDC) technologies (Angeles, 2005). RFID systems comprise three components: the tag or transponder, the reader, and the data processing subsystem containing both middle-ware and internal databases. RFID tags are active or passive. Active tags have internal batteries and can be utilized for longer distances since these tags are not dependent on a nearby field to transfer or obtain signals. Passive tags do not contain a battery or power source. RFID utilizes radio frequency waves to transmit the information between a reader and an item required to be identified, tracked, or located. RFID technology can identify objects without line of sight and with a greater reading distance compared to barcode technology. In addition, in contrast to barcode technology, RFIDs can store more data, maintain larger sets of unique IDs, and detect many tags at once in a single area, without human assistance. RFID reading systems can detect, scan, trace, and monitor items attached with RFID tags within the defined proximity of the reader. In addition, the IoT is an evolution in computer technology and communication with the purpose of linking items through the internet and RFID is one of the essential components of the IoT (Sarma et al., 2002; Thornton et al., 2006).

Figure 6 Tracking view for fleet of delivery maps on GIS.

The authenticity of the product and the absence of any tampering with supply chain transactions are essential for products in the food industry and healthcare. Blockchain is an emerging technology which is solving this problem by immutable distributed ledgers which are verified by a large number of server computers simultaneously (Helo and Hao, 2019).

Transportation vehicles are also increasingly being tracked. The automatic identification system (AIS) is an imperative collision avoidance system required by the international maritime organization (IMO) to be installed on ships. AIS devices transfer data to stations such as harbor authorities, equipment such as buoys, or search and rescue airplanes. Every individual vessel utilizing AIS devices is identified by a unique Maritime Mobile Service Identify (MMSI) number and IMO registry number. The data transition intervals can be 3 s to a few minutes and two VHF channels are employed to transfer the AIS information. The initial use of AIS in maritime safety has been extended to support logistics needs (Chen et al., 2016; Last et al., 2017). Similar solutions are available for commercial airfreight. Also, many road transportation companies have built full-scale fleet tracking of trucks and trailers within their own assets. Real-time tracking and tracing allow fast response on adjusting plans and updating estimates for supply chain actors. Fig. 6 is a tracking monitor used for the planning and control of a truck fleet. Real-time truck location is combined with a planned delivery schedule and deviations between planned and actual are constantly monitored.

Advanced Supply Chain Planning Systems (APS)

APS are information systems that utilize advanced solution approaches such as operations research, metaheuristics such as genetic algorithms or computer simulations to resolve supply chain planning problems. An APS must interact with enterprise systems (ES) to accomplish a synchronized workflow. APS is not a replacement for human planners, however, as the users of APS can always approve, adjust, or deny the outcome generated by an advance planning system. An APS is a computer planning system that delivers various function of SCM such as procurement, production, distribution, and sales at the strategic, tactical, and operational planning level (Stadtler, 2005; Vidoni and Vecchiotti, 2015). Fleischmann et al. (2005) described the characteristics of an APS as follows:

- *Integral planning:* APS plans for the entire supply chain and integrates from suppliers to customers of a single company or even a network of enterprises.
- *True optimization:* APS improves solutions by setting alternatives, objectives, and constraints for various planning problems and utilizes optimization planning approaches, such as deterministic and heuristics methods.

- *Hierarchical planning systems*: APS employs hierarchical planning systems which is a concession between practicability and consideration of interdependencies between the planning tasks. The APS contains different planning levels or modules incorporating decisions at long-term, mid-term, and short-term decision levels (Fleischmann and Meyr, 2003).
- *Strategic network planning (SNP)*: It comprises the quantitative elements of strategic planning and aspects of network design, such as facility location, stock size, or production capacities.
- *Demand planning (DP)*: It forecasts the future demand in a make-to-stock environment on mid-term aggregate and short-term basis.
- *Master planning (MP)*: It integrates the material flow of the supply chain as a whole for a mid-term planning horizon.
- *Production planning and scheduling (PP&S)*: It encompasses lot-sizing, machine assignment, scheduling, and sequencing in the short-term planning horizon.
- *Distribution Planning (DtP)*: It deals with mid-term tasks within distribution systems, such as regular transport links, delivery areas of warehouses, and resource allocation.
- *Transport planning (TP)*: It covers the short-term dispatching of shipments in the distribution and procurement side.
- *Demand fulfillment and available to promise (ATP)*: It concerns the arriving of customer orders and comprises the tasks of order promising, checking the availability of materials, due date setting and actions in case of shortage.

Modeling and Simulation

Utilizing simulation models for complicated systems has become more popular and practical. The simulation approach captures the behavior of all units, the interactions between entities, and the uncertainties associated with systems. Simulation methods can be classified into three types: (1) system dynamics, (2) agent-based modeling, and (3) discrete-event simulation (DES).

The system dynamics methodology includes developing the causal diagrams and policy-oriented simulation models that are unique to each problem setting. The main principle of system dynamics is that the complex behavior of organizational and social systems are derived from the balancing of feedbacks, reinforcing feedbacks, and the constant accumulation of people, materials, financial assets, information, and even psychological or biological states. A completed model may contain scores or equations alongside numerical inputs. Modeling is an iterative process of scope selection, hypothesis generation, causal diagramming, quantification, reliability testing, and policy analysis (Homer and Hirsch, 2006).

Agent-based modeling employs a bottom-up modeling approach and is considered a valuable method for decision support in SCM. The most distinguishing aspect of agent-based modeling simulation (ABMS) is the agent perspective, derived from a view that every system consists of agents. In ABMS, agents are individual entities and have diverse characteristics. In addition, agents have internal behaviors, allowing them to act autonomously, sense any conditions, which occur within the model at any time, and react with the appropriate response. Autonomous agents are also able to interact with other agents and the environment. In addition, the adaptive ABMS is a modeling method in which agents can change their behavior during the simulation as they learn (Macal, 2016; Rouzafzoon and Helo, 2018).

DES has been the mainstay of the operational research (OR) simulation community. DES models are process-oriented and employ a top-down modeling approach. The focus is on modeling the system in detail and is not on the entities. Queues are considered the core components of modeling and entities flow through a system. In addition, the attributes of entities are changed while they transfer through a system. DES was originally employed to resolve the uncertainties inherent in real systems and to deal with those complicated scenarios that are too complex to be resolved by mathematical methods. DES has been vastly implemented in the manufacturing domain. DES is an operational research technique that allows the users to evaluate the efficiency of the current system, assess various scenarios, and devise a new system. In addition, a DES can be employed to analyze resource utilization, to forecast the impact of modification on the flows of entities, and to examine the complex connections between different variables of a model (Jun et al., 1999; Siebers et al., 2010; Wang et al., 2018).

Fig. 7 shows an agent-based model of the transportation schedules of a fleet of collection trucks taking orders from four factories under dynamic demand. Various complex scenarios related to capacity planning and extreme conditions can be modeled in a relatively small development time.

Conclusions

Digital technologies are the salient drivers of supply chain development. Logistics information systems connect the top layers of SCM to execute daily tasks and interconnect various actors in the networks to access the same real-time information. Currently, the main technological drivers are:

- Cloud-based software applications taking place from on-time premises software by introducing software as a service (SaaS).
- Increasing use of artificial intelligence techniques for solving problems related to mathematical optimization, such as warehouse optimization, APS systems, and the vehicle route planning used in TMS.
- Use of big data and analytics is enabling organizations to make automated logistics decisions in real time (Waller and Fawcett, 2013).

Figure 7 Agent-based simulation of transportation schedules of a fleet of collection trucks (AnyLogic software).

- Tracking and tracing is becoming a requirement of logistics applications: blockchains are used to guarantee the authenticity, with various IoT systems providing information from the entire transportation network.
- Robotics and automation are interlinking information management systems with the execution of the tasks.

Introduction

In a global economic environment, which is increasingly competitive and uncertain, any company could remain competitive and efficient without working closely with external partners. The concept of supply chain management has emerged in this direction and aims to manage in an efficient way, physical, informational, and financial flows between all its actors, for permanent intra and interorganizational coordination and organizational agility. In addition, in the current context of sustainable development, environmental, social, and societal factors must be taken into consideration in the management of logistics processes.

This coordination in the supply chain involves relationships between its various partners—customers, suppliers of goods, third-party logistics service providers (3PLs). It is strategic since in most industries, 60%–80% of value-added services come from suppliers. In the case of 3PLs, Lieb and Bentz (2005) report that about 60% of fortune 500 companies in the United States have signed at least one contract with a 3PL. Similarly, the number of European companies engaging 3PLs has nearly doubled since 2000 and the European volume of 3PLs and SCM business in 2016 was around USD 173 billion, while total global revenues were over USD 802 billion (Langley, 2018).

In order to set up this interorganizational cooperation, however, the company must select a well-performing set of partners to meet its needs in terms of profitability and risk. This selection is a complex process because, on the one hand, it is multifunctional and involves purchasing actors as well as other skills and resources of society, and on the other hand, it is multicriteria because it takes into account various tangible and intangible criteria such as price, quality, flexibility, reputation, delivery, expertise, etc. This process is obviously related to the product or service complexity to be purchased. To solve this complex problem, several techniques and methods are proposed in the literature, mainly in the case of the selection of product suppliers.

In this article, we focus on the 3PL selection process according to two aspects: the first one aims to identify the main criteria proposed in this process, while the second one aims to understand and explain the evolution over time of the importance of these criteria. Thus, to understand these aspects, the first part of this article deals with 3PL characteristics, and presents the various services they offer. The second part presents, from a recent study on this subject, an analysis of the different criteria as well as the evolution of their importance. The last part summarizes the implications, limitations, and potential perspectives of future research.

Characteristics of 3PLs

A substantial volume of research has been carried out on the outsourcing of logistics, the objective of which is to entrust to a 3PL, all or part of the realization and sometimes of the design, of a customer's logistics activities, possibly involving the physical transfer of materials or personnel. This strategic and complex decision allows the customer to focus on its core business.

Although logistics outsourcing is associated with a loss of control of outsourced activities, a reduction in direct customer contact and the potential for 3PL opportunism, the growing interest in this area is motivated by several factors (Razzaque and Sheng, 1998; Selviaridis and Spring, 2007), such as:

- reduction of costs, thanks to the economies of scale generated by a 3PL or by a release of immobilized capital,
- transformation of fixed costs into variable costs, thus allowing a company to focus on its own resources (financial, human, etc.), production and know-how,
- better control of logistics costs,
- increased flexibility of a 3PL, derived from its market knowledge,
- privileged access to 3PL skills and expertise, and
- in the context of globalization, logistics outsourcing is a way to get closer to customers all over the world.

These 3PLs may perform, in whole or in part, the logistics activities of their customers, whether or not they own warehouses and transportation means; knowing, however, that many of them claim a growing global presence, such as DHL, Kuehne-Nagel, DB Schenker, and Geodis.

Warehousing - Storage - Warehouse - Bonded warehouse - Storage at three temperatures (+, -, 0) - Automation, etc.	Packaging - Packing - Custom packaging - Copacking - Kitting - Stuffing-stripping - Palletization, etc.	Sustainable logistics - Ecofriendly packaging - Returns management - Waste management - Electric vehicles, - Mega-truck, etc.	Customer services - Call centers - Logistics advice - After sales service - Billing for account - Direct marketing - Logistics in situ, etc.
Order management - Cross-docking - Comanufacturing - Merchandizing - Postponement - Pick by voice - Pick by vision, - Pick to light - Put to light, etc.	Information & communication technology - E-commerce - EDI, ERP, WMS, TMS - Control Tower - Front office solutions - RFID - Bar code - Digital solutions - Geolocation etc.	Transport-distribution - Modes of transport - National, international, and multimodal transport - Last mile delivery (LMD) - Transport at controlled temperature - Urban distribution - Express distribution - Customs engineering, etc.	

Figure 1 3PL services by logistics activity.

To achieve effective integration and coordination in supply chains, most 3PLs have expanded their offered services from traditional or basic services (transport and warehousing) to innovative and value-added services (Fulconis et al., 2016; Aguezzoul, 2019). Fig. 1 provides a categorization by logistics activity, of the main services offered by 3PLs. This evolution, diversification, and innovation in their service offers have allowed 3PLs to access increasingly important roles in their customers' supply chains, from simple operators of logistics operations to becoming integrators of logistics solutions, sometimes at the worldwide level.

In order to set up the outsourcing contract with a 3PL, however, the customer must first make a rigorous selection from a set of potential performants of the 3PL function; those that have met their initial requirements. The following section details the 3PL selection process in terms of criteria, as well as the evolution of their importance over recent years.

The 3PL Selection Process

Selection Criteria

Once the customer has decided to outsource its logistics processes, the next step is to determine a set of potential performants from which to choose a 3PL. This strategic decision is influenced by several factors such as price, quality, services offered, technology mobilized, reputation, and the professionalism of the 3PL. Moreover, in the context of trade globalization, new factors must be taken into account, such as cultural adequacy to the target markets, sustainable aspects, political stability, and security. These factors represent the customer's sources of added value, since the expertise of the 3PL, for example, allows the customer to distinguish itself from its competitors.

A detailed analysis of 67 articles dealing with the 3PL selection problem, and published during the period 1994–2013 in reputable journals in the fields of logistics, SCM, and purchasing, has allowed the identification of 11 main criteria (Aguezzoul, 2014). An extension of this study to 17 articles published during the period 2014–17 (Aguezzoul, 2019), allowed these criteria to be extended to 12 and for them to be classified in this order of importance—relationship, cost, quality, services, flexibility, ICT, delivery, professionalism, financial situation, physical equipment and infrastructure, location, reputation, and sustainable logistics. Each of these main criteria is defined by a set of sub-criteria (Table 1).

It should be noted that the majority of the studies analyzed (80%) are empirical, conducted mainly in Asian countries, particularly China and Taiwan. Furthermore, international transport and warehousing remain the most outsourced logistics activities. The use of international 3PLs offering international transport services is due to the globalization of markets; 3PLs are increasingly integrating into global and complex logistics chains.

In addition, the multicriteria approach is the most used in the 3PL selection process and continues to be enriched by other criteria, such as ICT and sustainable logistics (Aguezzoul and Pires, 2016; Aguezzoul and Paché, 2018). The list of criteria to be considered differs depending on the outsourced services. For example, in the case of international transport, criteria such as the relationship with the 3PL, delivery reliability, location, ICT, and reputation are important (Yayla et al., 2015; Hwang et al., 2016). Similarly, in the case of returns management, equipment, and storage capacity of the 3PL, ICT, environmental aspects, as well as the existing relationship with the customer, are the most used criteria (Guarnieri et al., 2015). Finally, the main criteria that affect the selection of national operators are ICT, financial stability, quality, and range of services offered (Solakivi and Ojala, 2017).

Table 1 Summary of evaluating criteria

Criteria	Definition and attributes
Relationship	It includes shared risks and rewards, ensure cooperation between the user and the 3PL. It also helps in controlling the 3PL opportunistic behavior. Reliability, truth, dependence, alliance, compatibility, reciprocity are among its attributes.
Cost	It refers to the total cost of logistics outsourcing. Its related attributes include price, cost reduction, low-cost distribution, expected leasing cost, operations cost, warehousing cost, and cost savings.
Quality	Quality of the 3PL includes many aspects such as commitment to continuous improvement, SQAS/ISO standards environment issues, and risk management.
Services	It is related to attributes such as breadth of services, characterization, and specialization of services, variety of available services, presale/postsale customer services, and value-added services.
Flexibility	Ability to adapt to changing customers' requirements and circumstances. Its attributes include ability to meet future requirement, capacity to accommodate and grow the client's business, flexibility index, responsiveness to target market or service requests, capability to handle specific business requirements, and time response capability.
ICT	ICT capacity is an important factor in improving internal and external capabilities of the 3PL. It facilitates the execution of logistics operations and the rapid exchange with its customers. Its related attributes include EDI, WMS, ERP, and CRM.
Delivery	It's represented by attributes such as time, on-time performance, on-time shipment and deliveries, delivery speed, accuracy of transit/delivery time, shipment delivery, and on-time delivery rate.
Professionalism	3PL exhibit sound knowledge of services in the industry and display punctuality and courtesy in the way they interact and present to the customers. It is characterized by attributes such as expertise, competence, and experience.
Financial position	A sound financial performance of the 3PL ensures continuity of service and regular upgrading of the equipment and services, which are used in logistics operations.
Physical equipment and infrastructure	It corresponds to physical equipment and infrastructure that the 3PL uses to facilitate execution of logistics operations of its customers. It's related to attributes such as hub, warehouse, materials handling equipment, and means of transport.
Location	It's related to attributes such as distribution coverage, geographical specialization and coverage, international scope, market coverage, shipment destinations, and distance.
Reputation	It refers to the opinion of the customers about how good is the 3PL in satisfying their needs. This is more relevant in the initial screening of 3PL.
Sustainable logistics	Its activities are such as pallet flow management, recycling, reuse, repair, and return management. Its attributes include energy consumption, CO2 emissions, congestion rate, and number or volume of returns.

Importance of Criteria

Table 2 compares the two studies discussed above and conducted on 3PL selection during different time periods, in order to illustrate the evolution of the importance of these various criteria. The rank of each criterion is deduced from the number of times it is cited in the articles analyzed.

From these results, several trends are observable. Over time, it seems that the relative importance of ICT has increased significantly, while that of cost is relatively lower than in the past. This overall increase in the relative importance of ICT is due to the change in customer/3PL relationships. Indeed, ICT has facilitated the rapid exchange of information, to build cooperative relationships between a 3PL and its customers, which are increasingly distant geographically, and finally, to expand their (sustainable) supply chains to other partners around the world. Moreover, and although largely underestimated so far in the literature, the social

Sustainable logistics	10	2.19	100
Total	456		

relationships between 3PL and their customers constitute an important dimension in generating trust and reducing both opportunism and informational asymmetries.

The criteria related to sustainable logistics, especially reverse logistics, have also become increasingly important, due to the ongoing development of sustainable supply chains. As for the proximity of geographic markets, it does not seem to be a determining factor. Finally, using the Pareto method, we deduce the result as shown in **Table 3**, which aggregate the number of citations of each criterion as well as its respective rank.

The criteria most commonly used during the period 1994–2018 are found to be in this order of importance: relationships, cost, quality, services, flexibility, ICT, delivery, and professionalism. These criteria represent a little less than 80%, while criteria related to financial position, equipment and infrastructure, location, reputation, and sustainable logistics represent just over 20%. As noted earlier and following the emergence of new ICT, relational performance is shown to be a stronger driver of customer loyalty than are costs. This could also be explained by the fact that customer/3PL collaboration could reduce logistics costs by, for example, setting up a pooling system which also reduces CO₂ emissions and improves the loading rate of vehicles.

Conclusions

In the work presented in this article, the main decision criteria used in practice in the 3PL selection process are reviewed. An analysis of the various studies published up to 2017 helps to identify the relative importance that companies place on the criteria they use in this process. Over the 2014–17 period, this relative importance has changed considerably as a result of the emergence of ICT, which has encouraged close collaboration between 3PLs and their customers, even globally. Moreover, with the development of sustainable supply chains, other criteria particularly related to returns activities and waste processing, are becoming increasingly important and prevalent in this selection. From a managerial point of view, the results of this study could serve as a guide, on the one hand, for companies in the planning of logistics outsourcing actions and, on the other hand, for new purchasing managers or logisticians in identifying criteria favored when negotiating with 3PLs.

Evaluation of Logistics Service Performance

Due to its influence on downstream customer experience and the cost implications for executing these logistical activities in the process, logistics service is an important element in logistics management in order for firms to competently manage their cargo movement activities. Providing quality services with the aim of meeting customer requirements at reasonable cost is essential for a firm to create customer satisfaction and loyalty, increasing its ability to compete in the market. Toward achieving this end, firms need to understand customer requirements with respect to the seven “Rights” in logistics management and to satisfy them fully. Logistics service performance evaluates organizational ability in logistics management to deliver the right product, in the right amount and the right condition, to the right location at the right time for the right customer at the right price (and cost). This seven “Rights” principle highlights the importance of handling cargo movements to satisfy customer requirements in an efficient, timely, and reliable manner (Rushton et al., 2014). In a broad sense, achieving the seven “Rights” in logistics services reflects the “Availability” of goods for customers, which is fundamental in logistics management for firms in any industry (Lai and Cheng, 2009).

There is no universal definition of logistics service performance and it depends on the contextual situations for application. Several studies have conceptualized the attributes used for evaluating a firm’s logistics service performance. For example, Stank et al. (1999) examined the logistics service performance of fast food restaurants and identified two critical aspects: operational performance and relational performance. While operational performance focuses on the characteristics of logistical services (e.g., timeliness, reliability, and cost), relational performance focuses on activities that can enhance a firm’s closeness to customers (e.g., the courtesy of employees and responsiveness to customer requests). Stank et al. (2003) operationalized the logistics service performance of third-party logistics firms in three performance dimensions: operational performance, relational performance, and cost performance. Murfield et al. (2017) examined logistics service performance for the online retail industry. They suggested that relational performance is less important in the online context as buyers and sellers are physically apart and the services provided are aimed at goods and not at people. In this context, logistics service performance is conceptualized as comprising three performance dimensions: consumers’ perceptions of availability, delivery timeliness, and product condition. In the airline industry, Farooq et al. (2018) emphasized that airline tangibles, terminal tangibles, personnel services, empathy, and airline image are five crucial dimensions of logistics service performance. Overall, it is important for managers to consider the contextual situations in determining the appropriate logistics service performance attributes for applications in their organizations.

There are studies highlighting the importance of examining logistics service performance from customers’ viewpoints because their satisfaction level is dependent on how they perceive the service quality. The focus is on assessing the gap in logistics service quality regarding the services desired by customers relative to their perceived service delivery. Furthermore, customers experience logistics service in three different stages, starting from their pre-purchase inquiry (e.g., written policy for services, delivery schedule) and in-purchase interaction (e.g., ease of payment, stock availability) through to post-purchase follow-up (e.g., product returns, alterations). It is vital that firms fulfill their customer requirements in these different service stages to improve their experience and satisfaction. Examples for pre-transaction stage logistics activities include a written statement of customer service policy, methods of ordering, accessibility of order personnel, and system flexibility, such as handling last minute or minimum quantity orders. For the transaction stage, example activities include stocking products in good condition, inventory availability, delivery time, and delivery reliability. The post-transaction stage includes activities such as product tracing and warranties, product substitution and returns procedures, as well as customer claims and complaints handling. Many firms have recognized the importance of balancing and improving their logistics activities in these different stages without a lopsided focus. For example, JD.com, one of the largest online retailers in China, emphasizes quality logistics services for its customers. In the pre-transaction stage, JD.com provides its customers with service policy statements in written form (e.g., to deliver customer orders within 24 hours upon order receipt). JD.com also operates a call center to answer customer enquiries before their purchase. In the transaction stage, JD.com can responsively handle the delivery of goods from its warehouses to fulfill customer orders. JD.com offers “same-day delivery” and “next-day delivery” services to its customers, such that their ordered goods can be delivered in a timely manner. In the post-transaction stage, customers

can trace their purchase orders online in real-time, while JD.com is able to promptly respond to customer complaints and efficiently handle returned products.

Customer Segments for Logistical Services

Logistics management can create value for customers in terms of achieving the seven “Rights,” reflecting an organizational objective to meet customer requirements at reasonable cost with product availability. However, the value creation process comes with costs. Is it always advisable for a firm to provide a 100% service level for its customers and meet their requirements fully? This 100% service level means that customers come to purchase a hundred times and get exactly what they want without discrepancy. If they can only get what they desired ninety times out of their hundred visits, the service level achieved is only 90%. Whether or not a firm provides a high service level depends on the importance of the product items and customers for the firm’s profitability. For “cash cow” items (or important customers such as VIPs), a firm needs to provide a 100% service level because they are core businesses (e.g., representing 80% of its total sales) and can bring in a steady flow of income. But for trivial items (e.g., representing less than 1% of its total sales), providing a 100% service level is unnecessary and costly, compromising the firm’s profitability due to excessively high logistics costs for handling and storage, but with low financial returns. This situation is particularly salient for retail fronts such as convenience stores, where physical retail space is limited and it is expensive to maintain a higher service level for trivial items. In this situation, an occasional stock-out can be a better logistics option.

As another example to illustrate, customers can demand as many as twenty service items for liner shipping services (e.g., on-line booking, tracking and tracing, customs clearance, high frequency of sailing, door-to-door service, consolidation service and temporary storage). Yet, it is not necessary to offer all these services as doing so can be very costly and uneconomical. It is crucial for firms to identify the critical ones (e.g., based on the 20/80 rule) and make their best efforts to ensure that these critical items are fully achieved. The 20/80 rule suggests an operations strategy that coverage of 20% of service items (e.g., offering and excelling in the four most desired shipping service items out of the twenty items in the above example) can satisfy 80% of the services required by customers (the remaining sixteen items are either not offered or offered at a low level of service due to high costs with low marginal economic returns). It is essential that firms balance and improve their logistics service with the incurred cost considered, so as to avoid providing a high service level with low economic returns. In this regard, they can be more selective in providing logistics services for their customers. One way to do so is to customize their logistics services to specifically cater for the desires of different customer segments based on their characteristics, such as demographic (e.g., age, sex, and occupation), geographic (e.g., domestic, international), behavioral (e.g., use frequency, customer loyalty), and product characteristics (product value, product durability).

The rationale is that customer segments vary in their requirements for logistics services. For example, timeliness is a crucial factor for delivery of fresh foods because such product items are perishable. Fresh foods need to be refrigerated at the right time and delivered to the right location in order to keep them in the right condition. For products characterized with high value, security and timeliness are important service aspects to emphasize in logistics operations. Firms are encouraged to create value for customers by achieving the seven “Rights” in logistics, so long as the activities are profitable. Doing so will require firms to better understand the requirements of their target customer segments and fulfill them at reasonable costs. It can be a waste in logistics management that firms provide the wrong service items that are not desired by the market and/or their targeted customer segments or, alternatively, even the right service items but to an excessively high service level with low marginal economic returns.

In view of the varying requirements of different customer segments for logistics services, a classification framework can be useful for managers to design, plan, and execute logistics operations in their organizations. In general, there are two broad product characteristics, namely product durability and product value, which can be used by firms to segment their customer groups characterized with different logistics service requirements. As nondurable products (e.g., fruits and fashion) have relatively shorter product life cycles, timeliness is a prioritized factor to emphasize in their logistics arrangements. In considering the liability aspect of high value products (e.g., electronics and jewelry), security and damage free handling are vital for processing these items in logistics operations. These two dimensions of product characteristics provide useful insights for firms to understand logistics service requirements and develop logistics operations strategy for handling different product categories with the classifications shown in Fig. 1.

In segment 1, the products are characterized by high durability and low value. Examples of such kinds of products include textiles, books, papers, and plastics. For this segment, firms can choose to offer simply standardized logistics services, such as warehousing, distribution and pick and pack to meet customer requirements at the right cost.

In segment 2, the products are characterized by low durability and low value. For such kinds of products, firms are advised to put special emphasis on the timeliness of their logistical services. Customers in this segment care more about whether orders can arrive at their locations as promised. For example, staple food (e.g., vegetables and fruit) need to arrive at the right time in order to keep the food healthy, fresh, and in the right condition.

In segment 3, the products are characterized by high durability and high value. As the financial value of the products is high, secure and reliable logistical handling for the product movement are especially emphasized by customers of this segment. Firms need to pay the utmost attention to ensure security in handling these product items (e.g., electrical appliances and automotive products) at the right quantity with the right condition throughout the logistics management process.

Figure 1 Product classifications based on their value and durability.

In segment 4, the products are characterized by low durability and high value. The storage and delivery of such products (e.g., healthcare products and tobacco) require an emphasis on delivery at the right time with the right quantity and condition.

In sum, product categories servicing different customer segments vary in their logistics service requirements. Managers are advised to understand the cost and service implications in designing and delivering the types and levels of logistics services catering to the needs of their targeted customer segments. While it is desirable for a firm to strive for excellence in their logistics services, the wastes caused by providing excessive services, unwanted by their customer segments, must be avoided.

Improvement of Logistics Service Performance

For logistics service improvements, many firms have taken initiatives to enhance their service capability and performance. In the process, they need to pay attention to both relational and operational aspects of logistics service in planning and executing their logistics activities to attain the seven “Rights.”

For the relational aspect, this is concerned with the effectiveness of servicing customer needs, that is, doing the right thing. Building strong relationships with customers is essential for firms to enhance their logistics service performance. Firms can organize training programs to improve their boundary-spanning employees’ ability to develop long-term relationships with customers. These employees are frontline staff who directly interact with customers and identify customer needs first. Training programs can develop their knowledge on how to interact with customers and satisfy their logistics needs well. In addition, it is critical for firms to establish customer relationship management (CRM) systems, which can help facilitate the collection, access, transfer, and analysis of customer information for planning operations strategy to improve their customer experience. Such CRM tools are helpful for firms to communicate with their customers and to respond promptly to their requests, including claims and complaints. Utilizing CRM can also make it easier for firms to generate and disseminate customers’ current and future logistics requirements throughout their organizational functions and along the supply chain for responsive actions. For example, SF Express, the logistics giant in China, has developed an “E-learning” mobile platform, which provides its employees with plentiful training materials to facilitate their knowledge acquisition. This learning platform is helpful for employees to keep themselves updated with the latest trends in the logistics industry and to cultivate their customer service skills (e.g., communication skills, problem-solving skills, and logistics operations skills). Moreover, SF Express has collaborated with SAP to set up their CRM system. This system compiles customer data across different communication channels (e.g., e-mail, telephone, and social media) operating in SF Express. It collects and stores information about customers’ contact information, purchase history, personal preferences for logistical services and feedback. The system can also help the company analyze the demands of different customer groups and suggest targeted marketing campaigns to improve customer relationships.

The operational aspect is concerned with the efficiency in providing quality services to meet customers’ requirements, that is, doing the things right. Performing logistics activities wrongly (e.g., delivery delay due to lack of planning) can be costly for firms to rectify, such as arranging product returns and rehandling. To improve logistics operations, firms need a mechanism to manage and control the logistics activities for continuous improvements (Lai et al., 2004). The six-sigma approach in quality management can be a viable way for firms to identify areas for continuous improvement actions to enhance the efficiency of their logistics management activities. This approach involving a continuous improvement cycle in the five DMAIC stages (Define-Measure-Analyze-Improve-Control), together with appropriate quality management tools, will be useful for firms to identify and eliminate inefficiency in their logistics operations. For the application of the six sigma approach, there are seven basic tools of quality management including process maps, check sheets, histograms, scatter plots, control charts, cause and effect diagrams, and Pareto analysis, as well as the seven new tools including the affinity diagram, interrelationship graph, tree diagrams, prioritization grid, matrix diagram, process decision program chart and activity network diagram. Firms will also find other quality management tools for performance measurement, such as the balanced scorecard and dashboards, useful for monitoring and controlling their logistics service performance.

On another note, technological development is a trend for logistics service performance improvement. For instance, technological tools such as electronic data interchange, warehouse management systems, and global positioning systems can help enhance the operational efficiency and service performance of firms. In recent years, firms have adopted the new "ABCD" technologies in response to the increasing customer expectations with the aim of enhancing their logistics efficiency. The "ABCD" refers to artificial intelligence (AI) (A), blockchain (B), cloud computing (C), and data analytics (D). These emerging technological developments are taking increasingly central roles in shaping logistics operations in many enterprises.

Artificial intelligence is a branch of information technology that copes with the automation of intelligent behavior. AI aims to utilize computers or machines that can process problems independently, in a manner similar to the way a human with appropriate training would do. Advances in AI applications are crucial to the service performance improvement of logistics activities. The use of AI-enabled robotics and autonomous vehicles is the physical embodiment of AI in logistics operations. Intelligent robotics can provide firms with effective high-speed sorting of letters and parcels. For example, JD.com has started to use robotics to move and sort parcels. The robots can automatically drive and "see" different items, and perform the tasks in a more efficient way than manual labor. The robots can sort 9000 parcels per hour in a warehouse center, which minimizes the amount of man-hour time it takes to complete the sorting tasks. In addition, JD.com has tried to use robots to deliver items. It has designed a four-wheeled drone, which can carry five packages at once and travel 20 km, if fully charged. SF Express has also tested the commercial unmanned aerial vehicle with a planning schedule to use it to deliver goods in rural areas, mountainous landscapes, and to islands.

Blockchain refers to the use of distributed ledger technology that can record transactions between multiple parties in a secure and permanent way. Blockchain technology can be used for any exchanges, contracts, tracing, and payments. It can enable data transparency and access among different stakeholders involved in the supply chain, because every transaction is recorded on a block and across multiple copies of the ledger that are distributed over many nodes. Due to the improved data transparency, blockchain technology can help build trust between different transaction parties along the supply chain. Firms can incorporate blockchain into their operations to improve supply chain transparency and traceability for their transactions. Operational data concerning how goods are made, where they come from, and how they are delivered can be stored in a blockchain-based system accessible to multiple companies in the supply chain. For instance, SF Express has used blockchain technology to build a traceable supply chain for improving its logistics operations. It has launched a project called "Fenghui GO" and incorporated a blockchain source code with the ID "Haito Goods." Consumers are required to scan traceable QR codes to reveal the product descriptions and the logistics information of the whole process. This technology helps increase the speed of flow of goods, as well as the transparency and traceability of the transaction process.

Cloud computing technology has begun to play a major role in logistics operations. It allows firms to access different types of data in real-time from anywhere via the internet and to deploy resources immediately in case responses are needed. For example, Cainiao, a technology company in China, has used the Alibaba cloud platform to build a "logistics cloud" that tracks packages at every stage of the supply chain. This platform provides real-time access to logistics information for both buyers and sellers. Cainiao also deploys logistics resources (e.g., vehicles) and performs analyses to optimize transportation routes through the Alibaba cloud. Cloud technology also allows real-time inventory management and data flow from the cloud helps firms more precisely control their inventory levels in response to demand fluctuations. For instance, Tencent, the technology giant in China, provides cloud services for numerous companies to help them better manage inventories. Through the Tencent cloud platform, firms can keep track of the stock movement and inventory levels in real-time and ensure that inventory information recorded in the platform is consistent with the actual inventory quantity stocked in the warehouse. This cloud-based technology provides a more accurate control of inventory levels for firms and helps reduce the incidences of stock-out. In addition, cloud computing technology can enable firms to more effectively monitor how equipment (e.g., vehicles and trays) is utilized and discover utilization patterns to better exploit abundance or to eliminate wasteful excess.

Data analytics technology brings an incredible potential for improving logistics operations and service performance. In contemporary logistics management, firms manage a massive flow of goods and meanwhile create huge amounts of data sets for their logistics planning and operations. Many companies have implemented a "data-driven" strategy to derive value from large-scale quantities of data (Singh et al., 2019). For example, Cainiao has applied big data techniques to optimize routing by analyzing comprehensive historical utilization of data collected from transit points and transportation routes. Through route optimization, the data analytics helps Cainiao save 260 million hours a day in delivery time. In addition, Hema Fresh, a new grocery retailer in China, has leveraged the power of big data to choose the locations for its supermarkets. It has applied big data techniques to analyze the number of active users of Alipay and estimate the purchasing power of users in a region. The data analytics helps Hema Fresh determine the supermarket locations where sufficient target customers may exist to support their operations. Hema Fresh can deliver online orders to customers within 30 minutes in a 3 km radius from each of its supermarkets. Learning about customer demand and satisfaction is also a promising application for big data techniques. For instance, JD.com has developed a secure database that includes massive customer shopping and feedback data. Using data analytics, JD.com can better understand customer preferences and satisfaction, creating a personalized shopping experience for them. In sum, all these emerging "ABCD" technological applications represent contemporary directions for firms to improve logistics service performance in their operations.

Further to technological adoption, environmental management is an increasingly important area for firms to seek improvements in their logistics service performance due to stakeholder pressure for environmental management practices (Vejvar et al., 2018). The rapid development in e-commerce and online retail sales in recent years has boosted the demand for logistics handling and delivery. The cargo movement processes can cause serious pollution and environmental damage, urging a need for greener service (Chan et al., 2016). For instance, there are increased greenhouse gas emissions by vehicles leading to poor air quality. The cargo movement

processes can also generate large amounts of waste, including wrapping materials and pallets. As such, it is essential that firms adopt green practices to lessen environmental damage and conserve resources in handling cargo movements, enhancing their logistics service performance (Lai et al., 2010). The increasing government pressures for environmental preservation have also urged firms to mitigate the operational damage they cause to the natural environment. In response, many enterprises in China have begun to embrace green practices as a part of their logistics service improvements. For instance, JD.com is proactive in implementing environmentally friendly initiatives. Some of its exemplary practices include the use of energy-efficient materials and handling equipment, automated loading, recyclable packaging and dissolvable materials, alternative fuels, electric vehicles and consolidated delivery. Overall, the environmental and sustainability management aspects are growing as important areas for firms to improve their logistics service performance.

Summary

In this chapter, we discuss the principles of logistics service performance with respect to the attainment of the seven “Rights” and the need for different treatments in different customer segments, as well as the emerging trends on technological adoption for logistics service performance improvements. Firms need to pay attention to different contextual situations which vary in the performance requirements for planning actions to improve their logistics services. There are also three stages of logistics services for customers that firms need to balance and improve for performance enhancement. The emerging “ABCD” technological applications and environmental management are the trending directions for firms to seek logistics service performance in the years ahead.

Introduction to the LPI

Logistics is understood as a network of services that support the physical movement of goods, trade across borders, and commerce within borders. It comprises an array of activities beyond transportation, including warehousing, brokerage, express delivery, terminal operations, and related data and information management. The global turnover generated by these networks exceeds US\$ 4.3 trillion (2018). Although logistics is global in nature, the quality and efficiency of logistics delivery actually available to traders or manufacturers in a given country, or part of a country, is contextual and depends on a series of local factors. The concept of logistics performance, proposed by the World Bank in 2007, captures these outcomes and helps understand the magnitude and consequences of differences in performance across the world.

Logistics performance is key to economic growth and competitiveness. It determines how effectively a country connects to global networks and accesses world markets. Inefficient logistics raises the cost of doing business and reduces the potential for both international and domestic integration. Research shows that logistics performance and freight connectivity have a higher impact on the costs of trade than geographical distance. The Logistics Performance Index (LPI) has been conceived as a synthetic metric of how well countries are connected.

On July 24, 2018 the World Bank published the sixth edition of Connecting to Compete, the biennial Logistics Performance Index report. The first LPI report was published in 2007 using an identical approach (Arvis et al., 2007), which allows for comparison over time, too. All LPI reports and their aggregated data are freely available in the public domain in an interactive format at: <http://lpi.worldbank.org/>.

The LPI report puts together views of logistics professionals in more than 160 countries about how easy or difficult it is in these countries to transport general merchandise. The LPI 2018 index is compiled based on almost 6000 country assessments made by logistics professionals, which are also highly relevant in a global sourcing context.

The LPI captures a broad range of factors affecting trade logistics performance. Its results show clear benefits, particularly for developing countries, in moving forward on a broad range of fronts to improve logistics. Of particular importance is the role of public policies in shaping logistics performance. Logistics service delivery and the efficiency of supply chains depend on public sector provisions and interventions in a number of domains. Logistics uses publicly funded or regulated infrastructure. International trade is processed by border agencies. Services and logistics activities are regulated with fiscal, environmental, safety, land use, or competition objectives. The World Bank's LPI reports have emphasized the contribution of consistent policy interventions in the areas of infrastructure, the regulation of services, skills or trade facilitation. Since 2007, the LPI has stimulated national initiatives in many countries around the world.

This paper uses the materials published in the LPI 2018 report (Arvis et al., 2018), and it aims to highlight the key elements and policy-making messages of the LPI 2018 report, which the reader is encouraged to explore in depth afterward by reading the initial report.

The LPI Methodology

The LPI survey data provide numerical evidence on how easy or difficult it is in these countries to transport general merchandise—typically manufactured products in unitized form. The 2018 LPI survey employed the same methodology as the previous five

editions of Connecting to Compete: a standardized questionnaire with two parts, the international and the domestic part, respectively (Arvis et al., 2007; Arvis et al., 2010, 2012; Arvis et al., 2014; Arvis et al., 2016).

In the international part of the questionnaire, respondents evaluate six indicators of logistics performance in up to eight of their main overseas partner countries. The six main indicators of the international part of the LPI summarize on a five-point scale the assessments of logistics professionals worldwide trading with the country. The six indicators used to construct the international LPI are:

1. The efficiency of customs and border management clearance,
2. The quality of trade- and transport-related infrastructure,
3. The ease of arranging competitively priced international shipments,
4. The competence and quality of logistics services,
5. The ability to track and trace consignments, and
6. The frequency with which shipments reach consignees within the scheduled or expected delivery time.

In the domestic questionnaire, respondents are asked to provide qualitative and quantitative data for the logistics environment in the country where they work. The domestic part of the LPI indicates the quality and availability of key logistics services within a country, but due to the small number of responses, these data are more informative in comparisons by region or income group.

The next LPI edition—scheduled for 2020/2021—will feature a methodological update. While previous LPI editions relied on perception-based data from surveys of logistics professionals, the new edition will be based on micro-performance data (vessel and shipment tracking) as the main input.

This is relevant for an endeavor such as the LPI, given the network structure of logistics. In addition to micro-level data, the revised methodology aims to incorporate geospatial data as well as data from online professional sources and social networks. The goal is to improve the current LPI by addressing its challenges, such as large year-on-year fluctuations in some countries' scores and ranks, and by building on the LPI's strengths as a comprehensive supply chain performance indicator.

Guidelines on How to Use the LPI and How to Interpret it

Since 2007, LPI findings have become standard reference material in numerous studies and policy papers on trade logistics. The LPI has been adopted by several countries and international organizations as a key performance indicator in their national transport or logistics strategies. This makes it important to highlight how best to use the LPI and its indicators to avoid possible misinterpretations.

In short, individual country data—especially rank positions tracked from one LPI report to the next—should preferably not be used as the sole indicator, but should be considered in combination with scores, while also keeping the size of the confidence intervals of these scores in mind. Using the weighted aggregate score and rank data that rely on the four latest LPI ratings (e.g., for years 2012–18) is also a good idea, as they provide a more balanced picture.

Logistics Performance Matters

An effective logistics sector is now recognized almost everywhere as one of the core enablers of development. Previous editions of Connecting to Compete have highlighted how implementing better policies leads to better logistics performance. Such policies cover, for example, regulating services; providing transportation infrastructure; implementing controls, especially for international goods; and raising the quality of public-private partnerships (PPPs).

The policy focus has evolved since 2007, when the first LPI report was published. Initially, logistics policies tended to concentrate on facilitating trade and removing border bottlenecks. Today, international logistics is increasingly intertwined with domestic logistics. Policy makers and stakeholders deal with a wide range of policies. Growing concerns include spatial planning; skills and resources for training; the environmental, social, and economic sustainability of the supply chain; and the resilience of the supply chain to disruption or disaster (physical or digital).

Gaps in Logistics Performance Persist

Overall, the score profile of the entire set of more than 160 countries has remained similar since the 2007 edition, which is an indication of the robust nature of the underlying data. (Table 1).

In 2018, the gap between top and bottom performers narrowed somewhat again, and the average score for the top 10 countries dropped to 4.03, whereas the bottom 10 countries scored an all-time high score of 2.08 (Fig. 1).

High-income countries occupied the top 10 rankings in 2018, eight in Europe plus Japan and Singapore—countries that have traditionally dominated the supply chain industry (Table 2). Germany is at the top, scoring 4.20. The scores of the following nine countries are in a tight interval, with Sweden in 2nd with a score of 4.05 and Finland in 10th with a score of 3.97. The composition of

Table 1 Top 10 average and lowest 10 average LPI scores, 2007–18

1=lowest; 5=highest	2007	2010	2012	2014	2016	2018
Top 10 average	4.06	4.01	4.01	3.99	4.13	4.03

the 15 best-performing countries has not significantly changed either. But it is worth highlighting major improvements in the LPI scores of Japan, Denmark, the United Arab Emirates, and New Zealand since 2012.

The bottom 10 countries are mostly low income and lower-middle-income countries in Africa or isolated areas (Table 3). Some are fragile economies affected by armed conflict, natural disasters and political unrest. Others are landlocked countries naturally challenged by geography or economies of scale in connecting to global supply chains. Afghanistan ranks 160th with a score 1.95, preceded by Angola (2.05), Burundi (2.06), and Niger (2.07).

The composition of the top-performing upper-middle-income economies has changed marginally, with China (26th with a score of 3.61), Thailand (32nd with a score of 3.41), and South Africa (33rd with a score of 3.38) leading the group (Table 4). Romania,

Croatia, and Bulgaria also improved their rankings. Among low-income countries, those in East and West Africa lead in this year's edition.

Among the lower-middle-income countries, large economies such as India (44th with a score of 3.18) and Indonesia (46th with a score of 3.15) and emerging economies such as Vietnam (39th with a score of 3.27) and Côte d'Ivoire (50th with a score of 3.08) stand out as top performers (**Table 5**). Most of these countries either have access to the sea or are located close to major transportation hubs.

Among low-income countries, countries in East and West Africa are leading performers in the 2018 report (**Table 6**).

Supply Chain Reliability and Service Quality are Strongly Associated with Logistics Performance

Supply chain reliability is key to logistics performance. In a global environment, consignees require a high degree of certainty as to when and how deliveries will take place. Reliability is typically much more important than speed, and many shippers are willing to pay a premium. In other words, supply chain predictability is a matter not just of time and cost, but also a component of shipment quality (Fig. 2).

In the top LPI quintile, just 13% of shipments fail to meet company quality criteria—the same proportion as in 2014 and 2016. By comparison, two to three times as many shipments in the two bottom quintiles fail to meet these criteria, and quality criteria in low-performing countries tend to be less rigid than in high-performing ones. This finding illustrates the persistence of the logistics gap from an overall perspective of supply chain efficiency and reliability.

The differing pace of progress is also seen in the ratings of domestic trade and transport infrastructure, where respondents were asked to assess how much these have improved since 2015. As in previous surveys, satisfaction with infrastructure quality varies by infrastructure type. For the first time, however, the perceived improvement is higher in the bottom quintile than in the top, although the difference is weaker in the middle of the distribution.

Respondents in all LPI quintiles are highly satisfied with information and communications technology (ICT) infrastructure. The infrastructure gap continues to narrow, particularly between the top and the bottom, where the rate of improvement seems noticeably faster. Improvement in the middle quintiles is on a par with what has been observed previously. In contrast to ICT, rail infrastructure continues to elicit general dissatisfaction. Similar patterns emerge when the domestic LPI data on infrastructure are disaggregated by World Bank region, excluding high-income countries. ICT is rated at the top or very close to the top in all regions.

Figure 2 Respondents reporting that shipments are "often" or "nearly always" cleared and delivered as scheduled, by LPI quintile. Source: Arvis et al., 2018.

Delivering Good Quality Services is Key to Successful Operations, and its Importance is Growing

The LPI has shown that service quality drives logistics performance in practically all economies. Yet developing advanced services, such as third-party or fourth-party logistics, requires following a complex policy agenda, partly because such services cannot be created from scratch or developed purely domestically. In logistics-friendly countries, manufacturers and traders already outsource much of their basic logistics operations to third-party providers and focus on pursuing their core business while managing more complex supply chain issues.

This handoff is reciprocal: the more that such advanced services are available at a reasonable cost, the more shippers will outsource their logistics. But the less that reliable and comprehensive service are available, the more shippers will handle logistics in house.

Logistics services are provided under very different operational environments globally. In a pattern recurring across years, the quality of the services that logistics firms provide is often perceived as better than the quality of the corresponding infrastructure that they operate. This may be explained partly by who the respondents are—freight forwarders and logistics firms rating their own services.

In a pattern seen across LPI editions, operations that support international trade, such as air and maritime transport and supporting services, tend to receive high scores even when infrastructure bottlenecks exist. Railroads, on the other hand, have low ratings almost everywhere. Low-income countries score poorly on road freight and warehousing.

Service quality can differ substantially at similar levels of perceived infrastructure quality. Even high-quality “hard” infrastructure cannot substitute for operational excellence, based on “soft” infrastructure such as professional skills and smooth business and administrative processes.

Supply Chain Resilience and Sustainability are Emerging Concerns

The resilience of international and domestic supply chains has emerged as a growing policy concern worldwide. Resilience is understood as the ability of an organization (or a country) to recover from severe disruptions, whether caused by humans or natural. For 2018, the LPI survey included a question on cyber security resilience. The perceived magnitude of cyber threats and preparedness to mitigate their effects go hand in hand (Fig. 3). Developing countries lag far behind high-income countries in both.

The 2018 LPI survey confirms that demand for sustainable supply chain management goes hand in hand with logistics performance. This is especially true for environmentally sustainable services (green logistics). In the top quintile of LPI performers, 28% of respondents indicated that shippers often or nearly always ask for environmentally friendly options. In the second-highest quintile, the share drops to 14%, and it falls steadily in the third (9%), fourth (7%), and fifth (5%) quintiles.

This trend is in line with the increasing number of global and national commitments to reduce freight- and logistics-related greenhouse gases, particulate matter and other harmful emissions. Regulatory changes have been implemented in all transport modes and the international targets for 2030 and 2050, for example, are ever more challenging.

Figure 3 Cyber security threats and preparedness by income. Source: *Arvis et al., 2018*.

Pushing the Envelope of Implementation

The implementation of effective policies to improve logistics performance is at least as challenging today as in 2007—for two reasons. First, the scope of implementation has widened from the traditional focus on infrastructure and trade facilitation. Sustainability and resilience receive more attention, and not only by developed countries, as do skills development and training, spatial dimensions of logistics, and the specificity of the regulatory and legal framework.

In addition to these emerging fields, regulatory reforms of the logistics services sectors are critical but remain challenging to implement in many developing countries. Regulatory improvements aim to improve the quality of service delivery, building on market mechanisms and private sector participation, in the sectors that constitute the core of logistics activities, such as trucking, brokerage, and terminal or warehousing operations. The broad and crosscutting logistics agenda challenge policy makers to make sense of which policy measures are needed, when, and using what resources.

Second, most reforms involve more than one agency and many stakeholders, slowing implementation, or even reversing it, if cooperative mechanisms are not sustainable. This problem is well known in developing countries for transport (for example, transport corridors) and trade facilitation (e.g., single-window trade facilitation).

For consistent and broad reforms and improvements, countries must deal with this complexity. But countries in the middle and lower tiers of performance are more deterred by weaker coordination mechanisms and private sector constituencies than countries with modern and innovative logistics sectors. Even though logistics services are provided overwhelmingly by the private sector, public sector actors, and institutions play an essential role, without which logistics competitiveness is unlikely to improve.

Administrative reforms can be rapid when countries with strong political reforms will align their efforts. In some cases, soft reforms in the facilitation of trade and transport were implemented with considerable impact even before hard infrastructure projects were completed. The soft reforms provided a higher and quicker return on investment than hard infrastructure. Examples can be found in low- and middle-income countries such as India, Lao PDR, Southern African countries, and Vietnam, as well as in high-income countries such as Oman.

Unfortunately, performance may be degraded by governance weaknesses and economic and social turmoil, as for some Arab countries in the 2016 and 2018 LPI reports. Low-performing countries with serious governance challenges (conflict-ridden or post-conflict countries and fragile states) are the most in need of attention from their neighbors and the international community.

Ultimately, countries that introduce far-reaching changes appear to be those that treat logistics as integral to the economy. They tend to combine policy perspectives, such as regulatory reform, trade facilitation, and trade and investment planning. Seamless interagency coordination and, above all, strong public–private dialogue characterizes the top performers. They offer very positive examples of coordinating and facilitating logistics bodies, some of them public–private institutions, such as the most famous one, the Dutch Dinalog.

The Policymaking and Business Impact of the Logistics Performance Index

Since its inception in 2007, the Connecting to Compete report has moved trade logistics firmly onto the policy agenda, even for countries that had not previously considered it. LPI results have also been used in many policy reports and documents prepared by multilateral organizations or the consultants they have engaged. The findings provide a worldwide general benchmark for the logistics industry and for logistics users.

LPI results have been embraced also by the academic community, as evidenced by the widespread use of LPI data in research reports, journal articles, and textbooks. The results have also been used in teaching, and thousands of theses at all levels have cited the LPI.

Logistics performance is based largely on reliable supply chains and predictable service delivery for traders. Global supply chains are becoming more and more complex. Ever more demanding regulatory requirements for traders and operators are motivated by safety, social, environmental, and other reasons. Efficient management and information technology solutions in both the private and public sectors are tools for high-quality logistics. National competitiveness depends on the ability to manage logistics in today's global business environment. More than ever, comprehensive reforms and long-term commitments are needed from policy makers and private stakeholders. The current LPI data provide a unique and updated reference for better understanding the impediments to trade logistics worldwide and for informing policymaking and business decisions.

Overview of Logistics Outsourcing

The term outsourcing consists of the words *outside*, *resource*, and *using*, respectively, and evolved in the 1970s and 1980s when companies found themselves facing increasing global competition. To resolve the prevailing lack of agility, many large companies decided to sell noncore activities and focus on their core business. At the same time, the deregulation of transport in the Western world facilitated companies to externalize their road freight transport. However, the growth of contracting out did not emerge until the change in managerial attitudes in the late 1980s. Due to rising cost pressures in the 1990s, the proportion of outsourced functions increased further, especially in the logistics area, but also in other fields such as information systems, human resources, or accounting (Pickles et al., 2016).

Outsourcing can be described as the execution and management of activities or functions by external specialized service providers and includes both material goods and services. Notable are the lack of a uniform definition and the existence of a variety of descriptions, as well as definitional inconsistencies, within the concept of outsourcing. It can be divided into partial and total outsourcing. While in partial outsourcing only certain tasks are transferred, in total outsourcing, an entire functional area is externalized and the corresponding functions are completely eliminated internally. In general, the outsourcing of functions aims at establishing long-term and lasting partnerships. However, the intensity of the cooperation can vary and, for example, be increased in order to overcome short-term bottlenecks. The opposite of outsourcing is represented by insourcing and is defined as the reintegration of processes back into the focal company.

Logistics constitutes one of the classic corporate functions and is one of the most frequently outsourced operations. In most industries, the majority of logistics costs are attributable to external service providers and a further increase in share is expected (Lemoine and Dagns, 2003). The reasons which prompt and favor the outsourcing of logistical functions are manifold, such as the increasing specialization of companies, the reduction of vertical integration and associated decreasing complexity, or the trend toward the lowering of high asset intensity of logistic functions, such as infrastructure for transportation, handling, or storage. In addition to the high resource intensity, the complexity of processes continues to increase due to the higher level of globalization, shorter lead-time expectations, and higher requirements for value-added processes. Further crucial aspects are the shift of production to low-cost economies, growing global brands and retailers, as well as the greater availability of information and communication technologies.

At the same time, logistics offers a wide range of specialized elements and, therefore, a large number of tasks that can be outsourced. Logistics services can be subdivided into four categories: transport services (e.g., internal transport, collection and distribution tours, route planning, and route optimization), handling services (e.g., loading and unloading, sorting, packing, and stowage optimization), warehousing services (e.g., storage and retrieval, order picking, quality inspection, and storage location management), and value-added services (e.g., filling, customs clearance, collection, and assembly work). The most frequently outsourced activities are domestic and international transport, warehousing, freight forwarding, and customs brokerage, which are all characterized by transactional, operational, and repetitive characteristics.

Logistics Service Providers

Logistics service providers form the core of outsourcing. In the literature, there are several possibilities for classification. A general differentiation is the classification into individual service providers, joint service providers, and system service providers. An

individual service provider offers a specialized range of services, while a joint service provider integrates several individual services and offers them to a broad customer field. In contrast, the system service provider is fully responsible for operating an integrated logistics system for one or more customers in long-term business relationships. Its special feature is the comprehensive range of services and the particularly high proportion of non-logistics applications.

The most commonly and intensively discussed concept to categorize service providers was developed by the management consultancy Accenture and classifies the basic types of logistics service providers according to their increasing integration into a customer's logistics chain. The classification encompasses first-party logistics (1PL) to fourth-party logistics (4PL) and lead logistics providers (LLPs). The 1PL (carrier) is a small entrepreneur or transport operator with core competence as a freight specialist or warehouse operator, high-handling competence, and a high level of service. The 1PL relies mainly on its own resources and is often used as a subcontractor. The second-party logistics (2PL) (operator) is a classic freight service provider for transport orders and, as a specialist for order logistics, can be compared with the joint service provider. The operator partly uses its own resources and has disposition centers and settlement systems. Its core competence is in order logistics with a focus on one mode of transport. By purchasing transport services on its own, the 2PL enables complex combined transports. This is achieved through its expertise in IT-supported processing systems and the processing competence across several carrier systems. The third-party logistics (3PL) (solution provider) offers comprehensive solutions and focuses on contract logistics in selected industries. It has its own resources in logistics, including warehouses and disposition areas, and its core competences are the provision of customer-specific solutions, the integration of the process chain regarding warehouse management, and the fulfillment of customer requirements. The 4PL (solution integrator), which emerged from the 3PL, is also specialized in individual solutions. The 4PL has a comprehensive expertise in the design, integration, coordination, and management of networks in individual industries but, in contrast, does not own assets in the field of classic logistics, such as trucks, warehouses, or distribution centers. This also applies to the LLP (solution designer). However, in contrast to the 4PL, the LLP does not act as an operator of the customer-specific solution itself. Its core competence lies in consulting.

The distinction between 3PL, 4PL, and LLP in the literature is often ambiguous due to overlapping tasks and responsibilities. This leads to diverse information about the share of the individual providers. In practice, several mixed forms of 3PL, 4PL, and LLP exist.

The Outsourcing Process and Determinants

The outsourcing process consists of a large number of complex, parallel activities. The implementation involves a variety of factors, circumstances, challenges, and potential effects, which have to be considered in a comprehensive context to be able to reach a reliable decision and ensure the success of the outsourcing procedure. Depending on the task to be outsourced, different priorities have to be defined, including strategic and operational aspects. Overall, regarding the single outsourcing phases, a high degree of transparency and rationality is required, which facilitates discussions and thereby consensus-building processes. Similar to the definition of providers, there is also a multitude of different procedure models for the process of outsourcing. In general, the procedure can be categorized into four phases: strategy, selection, design, and operation phase.

Strategy Phase

The strategy phase includes the description of the initial situation and the objectives, as well as the definition of the outsourcing strategy. The competitive situation, core competencies, and potential transaction costs are analyzed for an additional assessment of the strategic orientation. This also includes the definition of requirements for a suitable logistics service provider based on the previously defined outsourcing goals. The preparation of requirements, evaluation standards, control parameters, and further objectives is of particular importance, because the defined strategic aspects have a considerable influence on outsourcing success and can hardly be adapted subsequently. Furthermore, the definition and distribution of responsibilities, tasks, and decision-making powers have to be determined in order to exclude irritations and conflicts of competence.

Selection Phase

The selection phase deals with the choice of partners. First, a bidder preselection is conducted based on the previously developed requirement specifications. This is followed by the call for tenders, an evaluation, and bidder negotiations. For this purpose, the in-house production and external procurement costs are evaluated, which serve as the basis for the make-or-buy decision. Both the strategy and selection phase should be concluded with a comprehensive screening of the logistics service providers. The entire process is iterative in order to enable continuous improvement of the individual determinants and thus ensure the highest possible fit between the corporate cultures of the cooperation partners. In addition to the soft factors, the fit of hard factors, such as information systems or service level agreements, is guaranteed. Another success factor, which should be included, is the logistics service provider's focus on innovation and optimization, as these efforts will reflect the contractual partner's long-term aptitude and commitment. However, sustainable success can only be ensured through the pursuit of innovation and a fair sharing of the improvement potential.

Design Phase

The design phase includes all steps for the successful initiation of the outsourcing project. For this purpose, a consistent target vision of all parties must be created, which is followed by the definition of the structure and standardization of the interfaces and business processes. In addition, the respective resources, the transfer of personnel, and the cost structure have to be planned and recorded in a contract. With special regard to the design phase, decisions on competences and prices of outsourcing are important. However, the determination of competences from the customer's point of view is fraught with uncertainty. In order to ensure the success of outsourcing, reputation and references from previous project experience and perceived expertise of the service provider can be considered. However, this should not only be taken into account in the design but also in the preceding phases. The outsourcing of logistic processes plays a special role in this context, since in general a high degree of complex tasks is outsourced in comparison to other business areas, which at the same time require error-free integration. Despite the uniqueness of projects, the company's knowledge in outsourcing has a crucial impact, as the experience of already completed projects in logistics can be transferred.

Operation Phase

The operation phase comprises operational aspects for the successful maintenance of the outsourced tasks. During the ongoing operation, continuous management and control with a regulated exchange of information is essential and, to a large extent, determines the quality of the cooperation. In addition to the selection and design process, the implementation of the outsourcing project plays an important role. In contrast to the selection phase, mainly qualitative factors determine the success or failure of the implementation. The shift of company boundaries and the associated interventions in the process structures and resource distribution increase the cross-company interfaces and, thereby, the effort expended in coordination. This issue and the influence of outsourcing on many company processes require the implementation of multidisciplinary teams. Not only employees within the company and the logistics service provider must be involved, but also external stakeholders, as well as the top management.

Continuous and comprehensive communication within the business relationship reduces the risk of conflicts, strengthens trust, and prevents conflicts and opportunism (Swann, 2009). Communication can be divided into formal and informal. In contrast to informal communication, formal communication is based on predetermined communication channels and contents. Which information content and information channels are most important for the outsourcing partnership depends on the specific case, but both communication channels must be developed and enabled due to their complementary character. A further central element of the exchange of information is the regular controlling of the interfaces and the services to be provided within the outsourcing partnership. In this context, controlling does not simply rely on the control of the service provided, but the coordination and provision of information for optimization measures. Therefore, the open and cooperative exchange of relevant information is one of the most important determinants. In a successful partnership, long-term cooperative development with common goals should evolve as part of the outsourcing process. However, the partnership may also fail, resulting in a termination of the project and the reintegration of the tasks.

Potential Advantages and Risks of Logistics Outsourcing

The transfer of a company's own business processes to external partners is associated with both positive and negative consequences, which have to be analyzed extensively before a decision should be made. While some aspects apply to outsourcing in general, the outsourcing of logistic functions requires special consideration.

Advantages of Logistics Outsourcing

The decision to outsource logistics activities is primarily motivated by strategic and operational reasons, although a distinct assignment of the benefits to one of the two groups is difficult. The following description highlights the multitude of benefits of both groups and their interdependencies and illustrates the close link to a further important dimension: the cost-related dimension.

From a strategic point of view, outsourcing enables a generous variabilization of fixed costs. Transferring logistics activities reduces capital commitment and investment risks, as outsourcing companies have to allocate few resources to capital-intensive assets such as vehicles, warehouses, or information technology. These investments are carried by the logistics service provider itself, enabling outsourcing companies to focus their limited capital to a greater extent on their own core business areas and increase efficiency. Furthermore, obtaining the services from a third-party provider for a contractually agreed period guarantees strategic flexibility. This, in turn, allows the outsourcing company to continuously adapt the contracts to current market conditions or to change the service provider.

In addition, the transfer of nonbusiness-related logistics activities helps to reduce vertical integration, as well as internal complexity, enabling the companies to concentrate the released resources even more on their core competencies and strategically relevant operations. Most particularly, the coordinating support provided by a 4PL is gaining importance for a large number of suppliers and customers.

The operational side also benefits from a number of advantages from outsourcing. For example, by reducing the number of processes and the complexity, the degree of specialization of the remaining processes can be increased. In addition, outsourcing

allows access to the know-how of other external providers and reduces the danger of operational blindness. The operational execution of logistics processes by external service providers leads to higher productivity, flexibility, and quality of logistics services. This results in a multitude of advantages, such as faster lead times, improved on-time deliveries, less damage, and higher responsiveness to market changes. Logistics service providers are able to offer all the services at competitive prices, which cannot be realized internally by the outsourcing firm. On the one hand, this benefit is achieved through the advantage of volume-dependent cost depressions (economies of scale) due to the providers' high volumes and market shares. On the other hand, specialized logistics service providers are able to operate with lower personnel costs, mainly due to lower wage levels and working time regulations in the logistics sector compared to other industries, as well as the more rational use of personnel and higher personnel productivity.

The benefit of increased flexibility not only applies to deliveries to the end customer, but also within the company itself, since outsourcing usually allows for a decrease in workforce and enables the transfer of risks and intricacies regarding labor regulations or unions. Other risks that can be transferred are, for example, the rising costs of input factors (e.g., fuel), difficulties with fluctuations in transportation volumes, or customer changes to delivery requests.

With growing pressure to differentiate, service providers increasingly offer innovative solutions, which further improve the services and benefits for the outsourcing company. This includes, for example, not only value-added services, such as tracking and tracing or insurance services, but also the supply of concrete value-adding processes such as preassembly or quality control.

Finally, companies that engage in outsourcing also profit from two beneficial side effects. By conducting a comprehensive analysis of strengths and weaknesses, the basis is created for testing their own internal business processes against changed external conditions, and adapting them if necessary. Additionally, the input from independent third parties reduces the risk of a company's shortsightedness.

Risks of Logistics Outsourcing

The potential benefits of outsourcing are contrasted by risks, which could minimize or even negate the positive effects of outsourcing. Because of this, they have to be included in both the initial outsourcing decision and the subsequent evaluation of the partnership. One of the key benefits, cost reduction, is also a crucial potential risk at the same time. A common threat lies in the erroneous calculation of one's own cost structure, which can lead to a positive outsourcing decision even though the in-house costs might be lower. The reason for this is the insufficient cost accounting basis of companies, which often means costs cannot be calculated in detail and prevents sufficient differentiation between the individual logistics services.

In addition, the risk of being unable to achieve the calculated cost-saving potentials exists, which can be attributed to several aspects. First, companies may fail to reduce fixed costs to the necessary extent. This is the case if the released capacities cannot be reduced by the same amount or used for other purposes. Second, the total costs of outsourcing may be higher than planned due to hidden or underestimated costs. For example, the coordination effort between the partners and the corresponding transaction costs is often estimated at too low a level beforehand. Such additional costs during the project represent a large burden for the company, but may have a negative impact on the relationship with the partner as well. The higher coordination effort can also be seen as a form of complexity that counteracts the reduction in complexity previously mentioned in the advantages section.

Furthermore, companies increase their dependency through the transfer of formerly internal company processes and the disclosure of information. This disclosure leads to a vulnerability for opportunistic behavior from logistics service providers, for example, in the form of unexpected, subsequent price increases. Thereby, the dependency toward the contracted companies rises with an increasing specificity of the outsourced process or potential lost knowledge.

Despite careful preparation and selection, outsourcing partners can prove to be inefficient, which manifests itself, for example, in the inadequate quality of logistics services or noncompliance with delivery times. Since logistics service providers have direct contact with customers, but customers usually associate service quality with the focal company, the inadequate performance of the providers translates into an immediate damage of reputation for the client company. A contracting company can further be exposed to major reputational damage if the service provider becomes conspicuous through poor working conditions, exploitation of employees, or illegal practices. These aspects necessitate continuous monitoring and follow-up evaluation of the relationship with contracted logistics service providers.

A further risk, which could lead to the failure of the outsourcing project, is poor data exchange and poor communication between the partners. This can occur at any level of personnel and is another bottleneck for top-level performance. Mutual trust is an essential aspect, because the customer in particular must show a willingness to grant access to internal data, even if this leads to a disclosure and exposes the focal company to the risk of this data being misused or shared illicitly. Generally, the sovereignty over the controlling of logistics performance is lost, as the data are reported by the logistics service providers and they could provide embellished data. Preventing these issues would require further control mechanisms, which again would entail higher transaction costs.

Lastly, the advantage of risk shifting must also be considered in detail, as if the logistics service provider bears the risk on its own and gets into financial difficulties, the outsourcing company must provide financial support in order to further guarantee operational capability. This, in turn, puts the risks on the contracting company. This risk is particularly relevant for small logistics service providers, as their financial resources are limited. Empirical evidence also shows that many outsourcing projects only deliver suboptimal results, or even fail completely, because too little attention is paid to the initial strategic goal definition, cost analysis, and process design.

Issues and Influences

The characteristic of logistics to link companies, supply chains, and individuals globally exposes the field to economic, political, social, and technological developments and, therefore, leads to a changing environment for logistics outsourcing as well. Changes in the past were driven by a multitude of circumstances, such as constantly rising customer demands, the growing linkage between companies, and the evolution of information technology. Nowadays, the industry is influenced by even more factors and developments, which will change the requirements and design of logistics outsourcing operations further.

A fundamental change is the demand for sustainability, which will continue to rise in importance and significantly influence the logistics market. The increasing awareness in society of the need to reduce CO₂ emissions affects companies, the production of goods, and, as a consequence, transportation chains and decisions on outsourcing (Lieb and Lieb, 2010). In the future, companies will urge logistics service providers to carry out their freight transport using alternative means of transport with environmentally friendly power trains. Aggravating trends, such as the growing density of cities, severe traffic congestion, or possible daytime driving restrictions for deliveries, require a special focus on the last mile, as well as general alternatives for transportation (Zijm and Klumpp, 2017). Outsourcing companies will shift the development of solutions to these questions to logistics service providers. Ecological sustainability and corporate social responsibility will become established standards and lose their function as a differentiating feature for logistics service providers. The service providers, therefore, need to address new fields in order to distinguish themselves from the competition. Building on the earlier, outsourcing companies will call for further integrated solutions, instead of individual services, from additional value-added services to proposed solutions for traffic reduction, stockless warehouse operations close to high-density centers, or the management of reverse-logistics flows.

Another factor that will have a particular impact on future logistics outsourcing activities is the high volatility in markets, competition, and politics. Triggered by market changes, supply chain vulnerability, and optimization efforts, outsourcing companies will increasingly dynamically review and change the elements of their value chains. This requires logistics service providers to make their offerings more flexible in order to respond to the highly dynamic context. Therefore, both partners will have to intensify the networking and integration of their IT systems. Advances in information technology and the use of new technologies will create new types of collaboration, foster the reduction of risks associated with the exchange of internal information, and ensure increased security expectations.

Political developments that will influence the overall outsourcing strategies of companies refer to uncertainties regarding the openness of markets. For example, the European Union follows the strategy to facilitate the exchange of goods between all its member states, including the harmonization of taxes and legislation between their member countries. At the same time, the calls for protectionism intensify in many countries around the world. The country-specific developments particularly affect the cross-border movement of goods, but indirect consequences also impact the operations of regionally active service providers. Furthermore, legal issues such as new laws, increasing security regulations, and bureaucratization will influence outsourcing activities continuously.

Introduction

Just-in-Time (JIT), sometimes referred to as a “lean” system, is a management philosophy based on continuous search for improvement in ways to make processes more efficient. The goal is to produce goods and services without incurring any waste. JIT originated in Japan in the 1950s, helping Japanese companies, notably Toyota Motor Corporation, the world’s largest automaker, to enhance their productivities and cost efficiencies. Industry-wide diffusion of JIT was largely due to the 1973 oil embargo, and increased shortages of natural resources in Japan.

The Toyota Production System (TPS) is famous for elimination of “waste,” which was defined by Fujio Cho of Toyota as “ . . . anything other than the minimum amount of equipment, material, parts, and working time which are absolutely essential in production.” And Shigeo Shingo, the father of TPS, drew attention to the broad applicability of JIT by saying (Shingo, 1988) “ . . . the goal of improvement now is not simply to reduce the magnitude of problems, but to eliminate them entirely. Attention is focused on the causes of evils previously accepted as unavoidable, and steady progress is being made.”

JIT can thus trace its origins to *manufacturing*, TPS, and related approaches such as zero-inventory systems and zero-defect systems. Although there are subtle differences between the preceding, their similarities are what concern us here. Let us take as “given,” that the JIT system is well-suited to the appropriate manufacturing contexts.

The emphasis of this chapter, then, is on two questions:

- How can the methods and procedures of logistics and freight transport best enable a JIT production system to function well?
- And in designing those procedures, can we apply the JIT principles to logistics?

Our third and fourth sections, “Transportation in a JIT System” and “Inventory-Transportation Tradeoffs in JIT,” deal with the first question; the second is discussed in the sections that follow, on “Continuous Improvement and JIT Logistics” and “JIT-L and Sustainability.” Waste, in a logistics sense, includes excess inventory, inefficient routing of parts, and unnecessary movement or waiting. For example, delayed delivery of an order, due to a backorder at suppliers, is a waste. The extra time needed to deliver the order is of no value to the shipper.

The JIT approach is seen to involve potential cost-saving and is thereby a competitive strategy. JIT applications in business logistics concern, for example, the move-store activities within the supply chain. We will stress applications in the auto industry, both for historical reasons and because that industry has had excellent results in its utilization of JIT.

JIT Success, Pros and Cons

Following its stunning triumph at Toyota, the JIT approach reached North America a few decades ago. In the mid 1980s, General Motors decided to partner with Toyota to resuscitate its previously solely-owned auto-manufacturing plant in Fremont, California. That plant had needed to close after suffering low productivity indicators. This joint venture, naturally ingraining the JIT approach in its operations, showed tremendous success: Most of the laid-off plant workers were rehired. They were trained to improve

performance by eliminating waste. The morale of the workers increased, resulting in almost no absenteeism. The productivity and quality of the products drastically improved so much, that Fremont surpassed all other GM plants!

Such JIT success stories abound. This renewed definition of waste, and its accompanying goals of eliminating disruptions (e.g., quality problems during manufacturing) and of making the system flexible (e.g., faster setups), made JIT an eye-opener. JIT has become popular among other industries, including services and healthcare. Of course, the freight logistics industry is no exception in benefiting from the broad applicability of the JIT philosophy. Even more so in recent decades, firms realize that driving excessive logistics costs and wastes out of their supply chains emerges as a most viable competitive weapon for an enduring position in the marketplace.

Consider, for example, how Walmart became the world's largest retailer, via improving its logistics tactics by employing cross-docking. With the advent of emerging technologies in production (e.g., full automation) and transportation (such as increased use of drones in local deliveries and of driverless trucks for long-hauls), the JIT approach may be even more applicable in freight transportation and logistics systems.

As previously noted, JIT system benefits include decreased waste, lower costs, increased quality, cycle time reduction via eliminating non-value added operations, enhanced flexibility (from quick changeovers and smaller lot sizes), and improved productivity. Yet, JIT brings some drawbacks. For example, greater responsibility of workers may put extra stress on their shoulders; when unseen problems surface, the fewer available resources (time, people, inventory) may be insufficient to overcome supply chain disruptions, perhaps halting production. These pros and cons of JIT should be kept in mind. We also note that JIT involves cross-functional activities within an organization that extend to its supply chain. Within the firm, support from various functional groups (mainly operations, marketing, and finance), and between the supply chain agents, is essential if JIT is to achieve its full potential.

Transportation in a JIT System

A Possible JIT Contradiction

Here is an important issue, which a Just-In-Time system needs to address. Such a system famously delivers small quantities, repeatedly, rather than sending fewer, larger, "lot-size" quantities. Those JIT-type, frequent shipments, inbound to a manufacturing plant, likely worsen traffic congestion (a societal problem). More frequent deliveries of shipments result in extra vehicles on the roads, increasing emissions and creating noise pollution (environmental problems). The JIT approach does lower inventory cost by reducing necessary safety stocks, but JIT then increases transportation costs. Higher inventory costs associated with greater stock levels may be partly offset by savings in using less expensive transport (e.g., rail). However, in light of the considerable emissions due to (often unnecessary) frequent deliveries, the value of JIT-L needs to be justified.

Resolution of the preceding issue might again lie with suitable integration of an SCL (shipment consolidation) policy (Ülkü, 2009) and JIT-L. We provide several references, drawing attention to JIT's impact on traffic congestion (Rao et al., 1991), and the fact that SCL can reduce both costs and environmental damages (Ülkü, 2012). SCL and JIT-L can be considered side by side; both move largely less-than-truckload (LTL) type shipments. A parallel analysis of these two powerful logistics strategies is important.

Toyota Mixed-Load System

Can there be a system of *daily* deliveries to a plant, and still be consistent with zero waste (low emissions, fewer vehicles on the road)? The Toyota mixed-load system facilitates that. A group of five suppliers, say, would take turns on particular days of the week, in delivering its own components for that day plus having picked up the respective components of the other four suppliers. The truck of supplier A furnishes the transport on Monday, say, and supplier B plays that role on Tuesday, etc. This is analogous, of course, to a car pool taking children to school.

This mixed-load system enables, each day, deliveries of small amounts of each component (quantities required for that day's production). Perhaps equally important, a low-inventory system can now function in a "green" manner. That system permits daily deliveries of small quantities of the various items, without extra vehicles on the road or at the plant's loading dock.

Use of a JIT Warehouse

In Japan, the distances between suppliers and the (Toyota) plant are much smaller than in North America or Europe. The mixed-load system would be difficult to implement when the suppliers are that much further apart. Daily deliveries of the small quantities that the plant requires each day would be impractical (and also wasteful). While JIT is famous for its emphasis on minimal inventories, additional stocks may be required for a non-Japanese JIT system.

The solution is a "JIT warehouse." This would be operated by a 3PL, a third-party logistics service provider, and located as close (say a few kilometers away) to the assembly plant as practicable. Large (approximately TL) quantities of each component are shipped, for example, weekly, to the JIT Warehouse. The 3PL then makes daily, or even twice-daily, deliveries of the respective components to the proper loading docks at the plant.

It should be noted that expenses for warehousing and inventory are greater in this case than for the archetypal JIT system. Nevertheless, the total costs of inventory plus transportation in the above JIT system, as modified for application outside of Japan, is considerably less than it would be, if a “traditional” JIT approach were to be attempted.

Mode of Transportation

We tacitly assumed, above, that JIT transportation is by truck. And why not? Each shipper can dispatch goods by truck; any consignee can receive those loads. Not every supply-chain node has a rail siding, but those that do should not automatically assume that only shipments by truck can succeed in a JIT system. Indeed, the railways may be guilty of allowing the trucking industry to “eat their lunch.” A number of present or recent rail programs have been customized for JIT (Higginson and Bookbinder, 1990).

JIT transportation needs to be time-definite. Average speeds are slower for rail than for truck; when freight is hauled within a JIT system, the railway in question must give a *priority* to those dispatches. Shipment plans run by particular railroads were conceived for the JIT market. The French National Railway (SNCF) ran programs for JIT in which a commitment was made that the goods would arrive at particular destinations by a promised time. Dispatching decisions at intermediate nodes were made with this commitment in mind (Dejax and Bookbinder, 1991). The shipper paid a premium to receive this transportation service; a rebate was paid by the railway in the relatively rare cases that this commitment could not be honored.

In general, the application by a railroad of a shipment consolidation (SCL) program needs to be tempered in the case of JIT. SCL does typically lead to economies of scale in the cost per unit weight that is moved, or in cost per load, or cost per unit time. However, with those economies come some variability in the lengths of a consolidation cycle. The railway will receive a premium for a JIT shipment whose time commitment is kept; that premium is the benefit to the railway to roll back its SCL program, segregating JIT loads from the other (ordinary) shipments tendered to it.

When rail freight movements are part of a JIT system, the road in question must give priority to regularly-scheduled JIT trains. Those trains should, of course, bypass the classification yards. Within one of the railway intermodal plans, the pickup of goods from shippers, and delivery to consignees, should be prearranged, ideally in trucks owned by the railway or a carrier affiliate.

Outbound Versus Inbound Transportation

The above discussion on transportation aspects of JIT systems considered solely the inbound side, that is, daily deliveries of raw materials and components to, say, an assembly plant. Let us now discuss *outbound* transportation from a JIT manufacturing facility. That is, a distribution system, from that plant to warehouses and retailers. Can that outbound system also operate on a JIT basis? Is there any advantage in doing so?

Bookbinder and Locke (1986) conducted a simulation study of JIT distribution, whose main results are now summarized here. Two systems were compared, each consisting of a factory that served two warehouses that then shipped to three retailers apiece. Both systems operated on a JIT basis, with daily deliveries to restore the inventory at a given echelon to its base-stock value. In System 1, inventory was held at each echelon. System 2, however, carried inventories only at the factory and retailers; each warehouse in that system played the role of a cross-dock.

At each stock-keeping location, the performance metrics concerned the service measures P_1 and P_2 . These are respectively the probability of no stockout during a replenishment lead time (the cycle service level), and the fraction of demand that is immediately satisfied from on-hand stock (the fill rate). By the careful use of a simulation methodology, Systems 1 and 2 were compared in a statistical sense.

Naturally, System 2 had a greater annual inventory turnover, since it carried stock at one fewer echelon. This resulted in System 2 having a statistically significant lower cost than System 1. Both systems, however, could achieve high retailer service levels (whether P_1 or P_2), with only modest safety stock at the factory. A main conclusion is that, although the flows outbound from a JIT production system need not function in a JIT manner themselves, there is no reduction in retailer service levels in doing so. And there is a demonstrable cost advantage in operating that way. Of course, certain technical changes in the loading and unloading of JIT vehicles would enhance JIT's approach to distribution, rendering it smoother and more feasible.

Inventory-Transportation Tradeoffs in JIT

It is important to be aware that, in the analysis and operation of a JIT system, inventory decisions have tended to take priority over transportation. Two factors may explain this. First, we have already mentioned the geography of Japan, in which distances are “small,” and Tier-1 suppliers are located near the assembly plant. Short travel distances, especially when combined with the Toyota mixed-load system, make transportation costs seem less of an issue. Second, JIT became especially prominent in North America in the early 1980s. Interest rates went through the roof, generally greater than 20% annually. In that environment, it was no wonder that inventory was considered not an asset, but “waste.” Firms worried more about bank loans to finance their cycle stocks, than about the extra vehicles on the road, and the additional miles they were driving.

Today, companies and individuals are concerned about social responsibility, and the degree to which a supply chain is “green” (environmentally friendly). At present, interest rates are so low that, whether from a societal or a cost point of view, inventories look much better than transportation. Can this conclusion be supported by a modeling approach?

One way to study the issue of inventory-transportation tradeoffs is to consider the multiple-objective problem, $[\text{Min (Inventory Costs)}, \text{Min (Transportation Costs)}] = [\text{Min } Z_1, \text{Min } Z_2]$. Each objective could first be considered as a constraint on the other: $\text{Min } Z_1$, subject to the constraint $Z_2 \geq Z_{2 \min}$. The optimal values of the inventory costs would be found for good, feasible values of the transportation costs. Then, a reverse series of problems would be solved: $\text{Min } Z_2$, subject to $Z_1 \geq Z_{1 \min}$.

Here is why it may be necessary to consider a sequential method, similar to the preceding, but with a more detailed approach to the constraint on the secondary objective. In a firm with *decentralized* inventory and transportation departments, where we wish to minimize the total logistics costs, a simultaneous model to optimize those functions may not be implementable.

Bookbinder and Coulombe (2013) develop a sequential procedure, one that is applicable to any transportation-inventory model with separable costs. In that technique, there is first a full optimization by the “primary” department of its costs. The “secondary” department next minimizes its own costs, subject to a bounded allowable increase in the costs of the primary department. It was found that, when each department’s relative deviation from its optimal cost is equal, a near-optimal solution is attained for overall total logistics cost.

Continuous Improvement and JIT Logistics

The focus of JIT is on business processes, rather than on products and services. Therefore, tactics for Continuous Improvement, or CI (*kaizen* in Japanese), proven to be successful in manufacturing settings, can also be applied in business logistics (Coimbra, 2013). Let us call the application of JIT philosophy in the logistics context, *JIT-L*.

Increased competition, globalization, and a shift from manufacturing to more service-oriented industries especially in developed countries, necessitate finding innovative ways to cut costs by eliminating waste. Continuous improvement helps reveal nonvalue adding activities. One eliminates them if possible, or simply enhances the pertinent business processes, so that system performance metrics are constantly on an upswing.

How can we apply CI to *JIT-L*? We should start by understanding the core elements of logistics. These include customer service, order processing, inventory management, and of course, transportation. Customer service is a function of the quality with which the flow of goods is managed. Customer value-creation implies that a *JIT-L* system should observe the seven R’s of distribution: deliver in the *right* conditions the *right* product at the *right* quantity and *right* (least) costs to the *right* customer at the *right* place, and at the *right* time. With a closer look at customer needs, and after surveying feedback on customer satisfaction, the logistics service can benefit from informed decisions. For instance, even if a company’s on-time delivery performance is impressive, it may be nullified in terms of customer satisfaction and costs, if the delivered item is the *wrong* one to begin with.

Paperwork is still the “gum in the gear” in transport operations, especially in border-crossing operations. Such paperwork may cause delay in information flow between sellers and buyers, resulting in “waste” due to administrative procedures. For example, to reduce such unnecessary delays and therefore enhance on-time delivery performance, a 3PL could adopt electronic data interchange, Internet-based solutions, and Logistics 4.0 systems which are based on the Internet of things (IoT). The IoT refers to the data-communication technology and sensors that are built into physical objects, enabling those objects to be tracked and controlled over the internet. The IoT could provide valuable information and business insights, enabling logistics managers to reduce costs and upgrade service. For instance, an IoT-compatible forklift could alert a warehouse manager to potential mechanical or safety issues prior to their occurrence. The forklift could also provide increased visibility about inventory in the warehouse. If the related infrastructure were in place, it is apparent that the enabling technology may align with CI, and encourage progress in *JIT-L*. Venkatadri et al. (2016) investigate the use of the IoT and SCL in the context of integrated inventory-transportation management.

Due to its “pull system” nature, JIT systems are reactive; that is, production is initiated once the actual orders are received. Naturally, this reduces the amount of inventory (raw materials, WIP, or finished goods) to the level that is just needed. However, from a cost perspective, a JIT-embracing manufacturer may be still be lured to carry large volumes of stock. This could be due to price discounts offered by upstream suppliers, or simply to mitigate the risks of possible shortages. In such situations, the focal JIT firm can apply CI to magnify the precision in estimating demand, and also to forge stronger relations with its vendors. The “pricing” of inbound materials thus becomes a coordination issue, rather than a mechanism for the supplier to sell in volumes. Alternatively, as mentioned earlier, a JIT warehouse, especially in North America, may be a good “win-win” solution for both seller and buyer.

JIT-L should also strive to eliminate wasted capacity in transportation. For instance, because of inefficient truck scheduling, many vehicles could be waiting at the loading and unloading docks. Such unnecessary truck delays imply underutilized transport capacity, incurring obvious cost. Using advanced Logistics Information Systems (LIS; Bookbinder and Diltz, 1989), both the inbound and the outbound flows from the focal JIT company might be synchronized, similar to cross-docking. Bookbinder and Barkhouse (1993) propose such a system in terms of SCL, and discusses implications for JIT.

It should be noticed as well that, because of fewer handling activities (loading, unloading, sorting), the quality (condition) of goods delivered via SCL is better than that of separate shipments. This perspective could argue in favor of the use of SCL in a JIT setting: A pillar of JIT is quality; zero defects, until products reach the hands of the consignee.

Implementing JIT is not straightforward; many parts of the system must move together swimmingly. That necessitates the creation of dependable, long-lasting relations with supply chain partners. Therefore, JIT companies would tend to work with fewer

carriers, and more closely. As opposed to traditional firms, the JIT philosophy would dictate refraining from adversarial buyer-supplier negotiations. Rather, the focus should be on information sharing and developing “trust” between partners, to jointly make the most of mutual benefits in moving toward achieving the seven R’s. That is, CI needs to be embraced as a part of the organizational *culture* by all parties involved in the supply chain.

JIT-L and Sustainability

Daugherty and Spencer (1990) study the application of JIT principles to logistics and transportation. Let us now discuss the additional concept, “sustainability.” JIT logistics, whose aim is zero logistical waste, positively impacts three dimensions of sustainability: JIT-L yields economic benefits, because of reduced waste in motion and time (economic dimension). This is also reflected in diminished emissions of carbon and water, due to the elimination of the previously-mentioned unnecessary move-store activities (environmental dimension). Finally, JIT-L, by its management principles, requires close and prolonged relationships with relevant partners in the supply chain. JIT-L thus needs to be socially responsible in terms of how the involved organizations treat their employees, provide safe working environments, and support the communities involved (societal dimension).

The implementation of JIT-L can especially affect *omni-channel* marketing strategies. The consumer has the option of buying online, where, unlike in bricks-and-mortar retail stores, s/he is not able to physically examine the product and make a better informed purchase decision. That is, a holistic JIT-L system should consider the ramifications of product returns. The reverse flow of products is a significant issue, both in terms of cost and environmental impact. We need to factor in the impact of such reverse flows, with the recapture of value of the returned products.

Current models of closed-loop supply chains do not often embrace JIT-L. This might be because returned products may further benefit from SCL through designated collection depots. Although JIT “promises” zero-defects, we note that a large part of the items returned may not be due to product malfunction, but rather due to the consumers’ abuse of returns policies or simply regretting an impulsive purchase. (Ülkü et al., 2013; Ülkü and Gürler, 2018) analyze such consumer-return behavior and its impact on logistics performance indicators. Considering the fact that intense competition in the retailing world forces some companies to allow customers to return items for no reason at all, there is merit in exploring the impact of reverse logistics on JIT-L and its environmental footprint.

The JIT viewpoint implies complete elimination of waste from a productive system, whether it be a manufacturing, service, or logistics system. For CI to be achieved, the people in the system must contribute to it. Since, JIT requires constant feedback for improvement opportunities, and because employees are at the front line in observing what is going on in the business processes, it is of the utmost importance that the JIT-embracing company be respectful to its employees. Those personnel must be encouraged, so they are motivated to propose process improvement changes that may eliminate waste. Therefore, workers are essential assets of the JIT system, in which they are given additional authority to make decisions compared to more traditional (non-JIT) systems.

Concluding Remarks

The JIT approach originated in manufacturing, but is no longer confined there. As emphasized in this chapter, logistics and other business processes can benefit from the elimination of waste. The term “waste” should be understood as comprising any non-value added activities along the supply chain, such as unnecessary waiting times in loading and unloading, or underutilized conveyance capacity.

The emphasis of JIT-L is on rendering more “lean,” the move-store activities within and between supply chain partners. JIT-L obliges an integrated approach and dependable relationships between those partners.

Unlike their Japanese counterparts, North American firms are dispersed over larger areas, impeding the small distances that enable JIT success. Use of a “JIT warehouse” permits the JIT approach to function when suppliers to an assembly plant are not nearby.

JIT-L requires a real “cultural shift” in management to operationalize the concept of CI. But with that shift, JIT-L may enable new practices, especially with the advent of technology in the logistics sector. Similar to successful tactics such as cross-docking, JIT-L may show the way in novel areas such as the IoT (the “physical internet”; Venkatadri et al., 2016).

The JIT philosophy aids a renewed approach to supply chain sustainability. Logistical activities of course have an economic dimension (e.g., reduced waste in motion and time), but also environmental and social impacts of respective supply chains. Examples of the latter two effects include diminished carbon emissions by eliminating unnecessary move-store activities, and social responsibilities to the organization’s employees, respectively.

We remark in closing that JIT-L can easily be the subject of further research. Areas of interest include the reverse logistics of returned products, whose forward flows were managed as a JIT system, and the contractual mechanisms between partners in a JIT-operated supply chain.

Biographies

James H. Bookbinder is a Professor of Management Sciences at the University of Waterloo. For 20-plus years, he has worked with manufacturing firms, third parties, and transportation carriers on the modeling and analysis of logistics strategies and operations. He is the Director of WATMIMS, the University of Waterloo's Center for Research in Logistics and Manufacturing. He is a past-president of the Canadian Operational Research Society and past-chair of the transportation science and logistics section of INFORMS. Jim holds an MBA from the University of Toronto and a PhD from the University of California, San Diego.

His current research involves optimization of joint inventory-transportation decisions, and models for supply chains in the post-NAFTA, post-TPP (Trans Pacific Partnership) eras. For 10 years, Dr. Bookbinder was an Associate Editor (AE) of *Operations Research* (OR Practice), and still serves as an AE for the *Journal of Business Logistics* and for *Naval Research Logistics*. Jim is co-author of a 2009 INFORMS tutorial chapter on "Global Supply Chains." He is the editor of *Handbook of Global Logistics: Transportation in International Supply Chains* (Springer, 2013).

M. Ali Ülkü is a Professor and the Director of the Center for Research in Sustainable Supply Chain Analytics, in the Rowe School of Business at Dalhousie University, Canada. He received his PhD in Management Sciences from the University of Waterloo, MSc in Operations Research from Çukurova University, and BSc in Industrial Engineering from Bilkent University. Prior to his academic career, he worked as a productivity consultant at Anadolu Efes, the largest multinational brewery company in Turkey. Dr. Ülkü's writings include the theoretical modeling of sustainable supply chain and logistics systems, operations-marketing interface, and mathematical modeling of consumer behavior and societal problems. He is an avid supporter interdisciplinary research at the confluence of theory and practice. He published in such journals as *Annals of Operations Research*, *European Journal of Operational Research*, *International Journal of Production Economics*, *Journal of Business Research*, *Journal of Cleaner Production*, and *Service Science*. He served as the Program Chair for the 2018 Conference of the Canadian Operational Research Society.

Introduction

In the past, and even today, many companies had, and still have, high levels of capital bound up in the form of working capital in accounts payable, accounts receivable, or inventories. This capital cannot be used in a profit-yielding way. Thus, in the middle of the 20th century, many companies, supported by academic research, started to optimize their working capital positions on their balance sheets. The aim of the optimization focused on the company's benefit, and did not take into account the effects on other related parties in the supply chain. Moreover, at that time the main focus of companies was the flow of goods in the supply chain (thus, the physical supply chain), and not optimization of the flow of cash and affiliated information (thus, the financial supply chain). In the 1990s, however, supply chains became more and more globalized. With the development of direct sourcing, the complexity of supply chains increased, while the globalization of the economy lengthened the supply chains, by increasing tremendously the number of suppliers, and therefore the number of physical and financial transactions.

Since the global economic and financial crisis (starting in 2008/09), companies have had to rethink their supply chain optimization efforts, especially for financials. This crisis had two major negative effects on the world economy. First, the global demand for every kind of good and service collapsed, severely reducing the order inflow and backlog. Many companies have had to introduce short-time working or make staff redundant, or even cease their business activities. Second, liquidity was no longer available on the market, as financial institutions tightened their criteria for business financing, and increased the costs of financing. Since this credit crunch, the distance between investment grade and non-investment-grade financing rates has widened even more. Companies, which did not have sufficient liquidity, had to negotiate unfavorable conditions, or they went bankrupt. Both effects of the crisis destabilized supply chains as, for example, the timely supply of necessary product inputs was no longer guaranteed. Finally, this crisis clearly underscored the fact that a supply chain is only as financially strong as its weakest link.

In this context, the concept of supply chain finance (SCF) has been seen by companies as a suitable solution to reduce counterparty risk and sustainably stabilize the different links in their value networks, to prevent the disruption of whole production lines resulting from financial problems of one important party involved, and to optimize the total costs within the supply chain. SCF can be understood as a business practice whose principles were firstly examined by Koch (1948), who discusses the *economic aspects of inventory and receivables financing*, or Petersen and Rajan (1994), who emphasize *the benefits of lending relationships* from a small business perspective. SCF, in its contemporary manifestation, has come out of hibernation. In the meantime, SCF has become an established business practice, with an enormous range of techniques and solutions. Banks, fintechs, IT providers, advisors, logistics service providers, and others are forming an ecosystem for SCF.

This paper aims to provide an overview of the background, the relevance, and the definition of SCF. This paper also introduces the cash-to-cash (C2C) cycle as a key performance measurement of SCF. After the value proposition of SCF is elaborated, the solutions of SCF (especially the reverse factoring approach) are presented. Before the paper ends with concluding remarks, relevant internal and external stakeholders within the SCF ecosystem are discussed.

Historical Background of SCF

From a historical viewpoint, the industry of trade finance has been around for hundreds of years, with sample letters of credit from the 16th century on display at the museum of Banca Monte dei Paschi Di Siena in Italy (Malaket, 2014). Trade finance is a commercial discipline that divides into two opposing facets: on one side are letters of credit (L/C), standby credits, documentary collection, and bid bonds, all representing the traditional subdivision of trade finance. Typically, such traditional products of trade

finance address single transactions, and establish bilateral financing arrangements between a buyer and a seller involving other parties only if, and when, directly concerned. On the other side, the modern form of trade finance promotes financing programs occasioning the emergence of entire ecosystems of relationships. These contemporary interorganizational financing solutions signify an evolutionary step as they disassociate themselves from atomistic product-transaction thinking to a holistic solution-relationships rationale in supply chains. Thus, the modern method of trade finance formed the basis of SCF (Hofmann, 2005; Hofmann and Belin, 2011). In the not too distant past, businesses exchanging goods and services conceived of one another as autonomous entities, rather than constituents of the self-same supply chain. In need of liquidity and working capital, interdependent companies not only sought financing based on their own terms but also adopted ill-considered measures that got their trading partners in hot water (Dyckman, 2011). Many large US and European corporate buyers striving to optimize working capital, for instance, extended payment terms to the point that small- and medium-sized suppliers situated in states with less developed capital markets faced a sharp upsurge in production cost and financial risk (de Meijer and de Bruijn, 2013). Although lack of liquidity and financing is a menace ever-present with smaller companies anyway, multilayered developments induced a refrain from egocentrism and a turn toward cooperation in what may be considered a paradigmatic shift resulting in SCF, among others (Malaket, 2014).

The presumably most prominent calamity propelling the growth of SCF in recent years was the 2008/09 financial crisis in whose aftermath the implementation of Basel III impelled banks to hold sufficient high-quality liquid assets and intensified capital requirements, to name but a few amendments. While the Basel Committee on Banking Supervision's regulatory framework discourages banks from financing (typically) less creditworthy small- and medium-sized enterprises (a withdrawal of liquidity that halted the operation of quite a few small suppliers, and disrupted the supply chains of larger corporations in much the same way as the ill-advised extension of payment terms), and emphasizes SCF as a last resort, other developments deserve acknowledgment, too. The formation of SCF harks back to globalization and an increase in cross-border commerce, the contraction of traditional trade finance's letters of credit in favor of open account (O/A) trading, and enhanced technology facilitating automation and supply chain transparency. In point of fact, exchanging goods and services globally stretched supply chains, considerably incentivizing businesses to reduce capital exposure to supply chain risks by optimizing working capital. Although open account trading is one alternative to optimizing importers' working capital with their cost and cash flows under control, open account trading may jeopardize the health of exporters if employed without proper risk management measures. In light of this, the first movement by international banks toward SCF assuredly was not altruistic, but aspired to rejuvenate declining trade finance revenues. Although the industry of SCF continues to experience changes, with, for example, nonbank players entering the market, a further breakdown of SCF requires to emphasize a common understanding of its relevance at the minimum.

Relevance of SCF

Often, non-investment-grade companies and small-to-medium enterprises find it difficult to finance their working capital requirements, as buying firms have tightened their supply chains. This is particularly true for smaller suppliers or customers (buyers) in emerging economies. The result is that there is a significant credit arbitrage between large firms in established markets and their supply chain partners in emerging economies.

Referring to an interorganizational scale, single supply chain members often act against the supply chain surplus when achieving the same goal of improvement (Hofmann and Kotzab, 2010). Financial factors, such as credit risk and capital costs, are often transferred to the upstream supply chain (to suppliers), or, in fewer cases, to the downstream supply chain (to customers). Although extended payment terms on the supply side (or shorter payment terms on the demand side) constitute a lower risk to the buyer (vendor), self-centered payment terms can destabilize the entire supply chain, as a result of a higher-risk supplier (customer) base, and their restricted access to short-term financing (Seifert et al., 2013).

SCF aims to minimize the cost of tied-up capital, including its related risks, while maximizing the gains of cash received across the participating supply chain members. From an interorganizational perspective, firms with lower refinancing rates and greater financial strength should carry more working capital compared to firms with higher financing costs. Grosse-Ruyken et al. (2011) agreed that working capital management (WCM) decisions should consider up- and downstream partners in a collaborative way, and that an adequate level of working capital depends on the business model, specific design configurations, as well as risk aspects within the supply chain.

Definition of SCF

The term "supply chain finance" often refers to a branch of WCM, and is connected to financial supply chain management (FSCM). FSCM comprises the financial processes (e.g., customs clearance or invoicing) and payments within a supply chain, with the purpose of introducing measures to optimize planning, managing, and controlling cash flows, to facilitate efficient material flows in interorganizational settings. There are different understandings of SCF (Zhao and Huchzermeier, 2018):

- *Supply chain finance in the narrow sense:* Within this definition, SCF is understood as a financing solution that enables a customer to prefinance payables to suppliers. This form of supplier financing—also known as buyer-driven payables solutions—is the most common SCF practice. Such a common used instrument is "reverse factoring."

- *Supply chain finance in a wider sense:* However, SCF encompasses much more. The concept covers the financial flows of the entire supply chain and extends far beyond supplier financing. It aims to optimize cross-company working capital and the integration of financial processes between suppliers, customers, and external service providers (e.g., banks, fintechs, and logistics service providers). Thus, SCF can be understood as an approach to creating value by planning, monitoring, and steering the flow of financial resources for two or more organizations in a supply chain, including external service providers.
- *Supply chain finance in the broadest sense:* In the broadest definition, SCF covers not only the financing of all the transactions being done in supply chains (current assets), but also the financing of all resources and capacities required for operating activities (fixed assets). In particular, this includes moveable assets (e.g., vehicles), equipment (e.g., tools and machinery), and real estate (e.g., warehouses). Furthermore, this perspective goes beyond the point-in-time view, focusing, on the contrary, on the whole lifetime of the supply chain-relevant infrastructure.

In support of standardization efforts by the European Banking Association's Supply Chain Working Group, SCF refers to (EBA, 2014, p. 44): "The use of financial instruments, practices and technologies to optimise the management of the working capital and liquidity tied up in supply chain processes for collaborating business partners. SCF is largely 'event-driven'. Each intervention (finance, risk mitigation or payment) in the financial supply chain is driven by an event in the physical supply chain. The development of advanced technologies to track and control events in the physical supply chain creates opportunities to automate the initiation of SCF interventions."

Measuring the Performance of SCF

On the face of it, net working capital is defined as current assets minus current liabilities. In somewhat greater detail, working capital is calculated as working capital = accounts receivable + inventory – accounts payable + cash (EBA, 2014). Although holding more cash and inventory (i.e., raw material, work in progress, and finished goods), and accounts receivable (i.e., the money customers owe a business) increases working capital, adding accounts payable (i.e., the payments due to suppliers in exchange for their goods and services) decreases working capital. Although research suggests that a low level of positive working capital performs best, each company has to find the right balance between positive and negative working capital. That is, extraordinarily broadly speaking, positive working capital comes with less risk, but greater cost of capital, as expensive liquid assets are relatively abundant; negative working capital is accompanied by greater risk, but less cost of capital, as expensive liquid assets are relatively scarce. Nonetheless, optimizing working capital necessitates ways and means to draw conclusions pertaining to the commercial efficiency and effectiveness of WCM. Appealing to the time-based ratios of days sales outstanding (DSO), days inventory held (DIH), and days payable outstanding (DPO) together is one such approach to evaluating WCM. The C2C cycle, measured as $C2C\ cycle = DSO + DIH - DPO$, links the three time-based ratios, with the intent of demonstrating the period of time between disbursing cash for purchasing inventory and collecting cash for selling inventory. Considered in isolation (Hofmann and Belin, 2011):

- DSO portrays the average number of days required to collect outstanding receivables. Accordingly, DSO illustrates how fast customers are invoiced and payments received.
- DIH portrays the average number of days, raw materials, work in progress, and finished goods are held until sold. Accordingly, DIH illustrates how long funds remain tied up in inventory.
- DPO portrays the average number of days required to pay suppliers. Accordingly, DPO illustrates a trade-off between sufficient working capital and sustainable business relations.

As a local improvement can have negative effects on the C2C cycle of the previous and/or following supply chain partners, a holistic approach must be taken, creating a win-win situation for all involved parties. This requires that companies share their financial information concerning the weighted average costs of capital (WACC) and inventory carrying costs (ICC), to leverage financial strengths throughout the whole supply chain. The C2C cycle would be optimized so that it is inversely related to the companies' WACCs and ICCs, as the firm with lower costs of capital should carry more C2C cycle days. Degradation of one company's C2C numbers must be accepted, as it brings overall gains for the whole supply chain. These gains, for example, cost savings, have to be spread equitably, thus also compensating companies that reduce their profits. Further benefits include improved overall cash flows, and, thus, increased profitability and higher company value.

Value Proposition of SCF

Starting from the premise that SCF is set to optimize working capital, the following insights may eventually be pinpointed. First, the C2C cycle is said to be negatively correlated to the enterprise value. Changes in enterprise value can be described with the return on net assets (RONA). In line with this train of thought, optimizing working capital, too, adds economic value: optimizing the working capital intends to shorten the C2C cycle, which again increases enterprise value, an added value measured by RONA. Put differently, a chain of causation links working capital optimization, C2C cycle, enterprise value, and RONA. As is well known, SCF and its solutions are envisioned to optimize working capital, too.

Consequently, the value proposition of SCF incorporates at least two kinds of benefits for the parties involved. Qualitative benefits include an increase in payment transparency, an improved flow of information, and enhanced compliance and

relationships between buyers and suppliers (Templar et al., 2016). Quantitative benefits incorporate improvements in working capital due to reduced C2C cycle times, a reduction of operational and administrative costs, and increased liquidity (Caniato et al., 2016). However, from an interorganizational perspective, the shifts in the payment terms or program structure may result in a different allocation of benefits between the actors (Liebl et al., 2016). As an example, an improvement in the DPO from the buyer's perspective does not necessarily lead to a beneficial situation for the supplier, or the additional administrative effort needed for an SCF program may lead to resistance from within a company. Therefore, it is crucial to consider the actors' interests and motivations, to support the win-win concept of SCF.

SCF Solutions

SCF is different from traditional trade finance in that it elicits ecosystems of relationships. For such ecosystems to materialize, two elements are needed: an SCF solution and stakeholders of SCF. In point of fact, this combination motivates the market players to think in terms of a larger, generic ecosystem in which all sorts of stakeholders interrelate, irrespective of the specific solution.

The following SCF solutions are available:

- Accounts payable or buyer-centric solutions, comprising approved payables finance or reverse factoring, dynamic discounting or purchase order financing. Of the earlier, this category includes payables-based credit arbitrage or supplier finance and import financing.
- Accounts receivable or supplier-centric solutions, comprising receivables purchase, invoice discounting, factoring, and forfaiting. Of the earlier, this category includes key accounts receivable sales, sales finance, export financing, and the matching accounts receivable solutions.
- Inventory-centric or pre-shipment-centric solutions, comprising off- and on-balance inventory financing. Off-balance inventory financing refers to the financing of inventories where operational goods logistics and ownership are transferred to an external (logistics) service provider. In contrast, within the on-balance solution, inventories remain on the company's balance sheet, and serve as a guarantee for a credit agreement (the asset-based lending approach).
- Other SCF-related solutions, comprising asset financing and asset-based lending, longer-term export and project finance, bank payment obligations, hedging and payment instruments, and products of traditional trade finance.

Example: Approved payables financing is a branch of SCF, and focuses on the accounts payable aspect of WCM (Wuttke et al., 2013). From this branch, a commonly used program is called "reverse factoring." Reverse factoring (RF) is a buyer-driven payables solution (Klapper, 2005), and is commonly defined as an arrangement of a buyer and its supplier collaborating with a financier or bank to facilitate the optimization of financial flows along their respective supply chains (Liebl et al., 2016). RF first emerged as a financing solution for larger corporations, with the goal of diminishing the financing issues of their suppliers (Lekkakos and Serrano, 2016). Unlike factoring, RF is not the supplier asking the bank for anticipated credit, but the buyer initiating a reverse factoring program by offering the accounts receivable of its suppliers to a bank, once the product and the invoice have been sent by the supplier and received by the buyer (Zhao and Huchzermeier, 2018).

Fig. 1 illustrates the concept of reverse factoring, and the main parties involved in the process. The following explanation of the concept and its components is based on depictions in literature (Hofmann and Belin, 2011; Templar et al., 2016; Hofmann et al., 2018). The four parties are the affiliated suppliers or vendors, the initiating buyer, the financier, and the SCF platform

Figure 1 The concept of reverse factoring.

provider serving as the intermediary in the process, which can either be the financier directly or an independent service provider. Further, from the buyer's perspective, it is possible to interact with multiple suppliers and financiers at once, to establish a fully efficient reverse factoring cycle. The whole process starts with the buyer placing the order and the supplier sending the goods (1). Then, the supplier submits the invoice for the transaction to the buyer through the SCF intermediary, or any other form of invoicing favored by the buyer (2). This allows the buyer to receive the invoice in their enterprise resource planning system (3). Once the buyer approves the payable, the approval is conveyed through the SCF platform to the supplier (4). At this point, the supplier has the choice of waiting for the payment to reach its maturity or requesting an early payment executed by the financier (5). If the supplier chooses the financing method, the financier approves the early payment request through the platform (6), pays the receivable amount of the invoice (7), and earns the premium by withholding a small portion of the invoice payment as a discount (8). In the final step, when the invoice reaches maturity, the buyer pays the full amount of the invoice to the financier (9).

It becomes evident when examining the reverse factoring concept that the complexity and number of interactions between the actors may lead to complications and issues (Liebl et al., 2016). Therefore, it is crucial to better understand which individuals and groups within these parties are involved in the process, and what role they play in an SCF program.

SCF Stakeholders

A successful implementation of SCF requires a profound collaboration between all relevant parties. The working relationship has to evolve into a truly intensive partnership, in which all parties pay careful attention to the impact of their decisions on others in the supply chain. In view of the cross-functional nature of SCF, close coordination between individual internal and external stakeholders is required.

Internal stakeholders are responsible for successfully implementing SCF solutions. Be it sales dealing with DSO, treasury managing cash, procurement addressing DPO, or supply chain managers, together with manufacturing, planning inventory, these and other stakeholders internal to businesses are part and parcel of SCF ecosystems. With purposes and objectives contrasting in large part, the stakeholders within a company effectively constitute risk sources, just as organizations as a whole do. Staff from procurement and logistics must work closely with colleagues from the finance department to ensure a united front in dialogue with suppliers. The traditional job profiles and skill sets of the individual stakeholders must be improved in a targeted way, using SCF expertise, and a common understanding of SCF must be established.

External stakeholders have to be addressed, too: corporate customers, banks, nonbank financial providers, IT vendors, business-to-business networks and e-invoicing service providers, marketplaces and hubs, consultancies, logistics services providers (LSPs), industry associations and governments, along with the public sector. Apparently, this is a rich landscape not yet accounted for; for instance, a supply chain's upstream suppliers and downstream buyers in international contexts are often referred to as exporters and importers, of first, second, and higher tiers. To not lose a grip on feasibility, however, it is imperative to pare the external stakeholders down to the following vital ones:

- The focal company is usually an international enterprise sufficient in sales and trade volume to cater to the cost and sophistication of SCF. As the availability of buyer- and supplier-centric solutions indicate, the focal company is interchangeably a buyer or a supplier driving the adoption of SCF solutions in its supply chain.
- The trading partners, that is, first-tier suppliers and buyers, exchange goods and services with the focal company. Usually smaller than the focal company, the trading partners benefit from the adoption of SCF in ways that are subject to the solution in question.
- The service providers, that is, financial services providers (FSPs), LSPs, and insurance companies (ICs). FSPs are banks and nonbank providers of financial services. Banks, both international and national, facilitate the adoption of SCF on a stand-alone basis or in partnership with other banks and nonbank FSPs. Nonbank FSPs are financial arms of corporations, among others. LSPs offer a range of services, giving them insight into the physical supply chain. ICs assume the risk of incurring damage from certain negative events, for an insurance premium.

In practice, it is not always easy to convince internal departments of an SCF solution, while also taking account of the concerns of external stakeholders, such as suppliers and auditors. Auditors, in particular, should be involved at an early stage (i.e., when the SCF program is being structured), to obtain their evaluation of the compliance on accounting treatments and of the impact on financial reporting. The persuasive efforts are worthwhile, as customers who proactively offer their suppliers earlier payments through an SCF program enjoy clear competitive advantages.

Concluding Remarks

With the current advances in technological developments (e.g., automation, platforms, blockchain technology solutions [e.g., tokenization], and machine learning), the supply chain has become a cheap source of cash in many organizations (Hofmann et al., 2018). SCF enables managers to improve the company's balance sheet and income statement. There is a symbiotic effect between the combination of supply chain management and finance that makes the whole greater than the sum of the parts.

SCF can bring structure and discipline to the financial portion of the supply chain, which can, in turn, improve the physical supply chain. SCF can reduce the variability of payments in the supply chain and, therefore, can reduce the need for additional cash to alleviate uncertainty. In general, SCF has the strong potential to be a multiple-win for the ecosystem partners, with numerous additional benefits, such as providing significant liquidity, enforcing discipline in the approval of invoices, reducing risks, and taking the variability out of the timing of payments.

In a more comprehensive view, SCF addresses all the assets to be financed within the supply chain. Beyond the (net) working capital, SCF should contain all other necessary material resources (e.g., warehouses, trucks, and transshipment facilities), enabling infrastructures (e.g., information and communication systems, platforms, and software) or even human resources (e.g., workforce, truck drivers, IT specialists, and analysts).

Biography

Prof. Erik Hofmann (Dr. rer. pol., University of Technology, Darmstadt, Germany) is director of the Institute of Supply Chain Management and a senior lecturer at the University of St. Gallen, Switzerland. He is also head of the Supply Chain Finance Lab (SCF Lab). His primary research focuses on supply management and the intersections of operations management and finance issues. He has published in several operations management journals. He is coauthor of several award-winning books, including *Supply Chain Finance Solutions*, *Ways Out of the Working Capital Trap*, *Performance Measurement and Incentive Systems in Purchasing* (all Gabler Springer), and *Financing the End-to-End Supply Chain* (Kogan Page).

Introduction

In increasingly turbulent and volatile markets, where competition is not so much between firms as between supply chains, organizations must design and implement initiatives to increase their competitiveness. Recent years have witnessed the appearance of four situations which, just like a perfect storm, are significantly affecting the efficiency and sustainability of supply chains: the globalization of purchases and sales; a constant increase in raw materials prices, particularly oil; the sudden arrival and implementation of new materials and production processes; and finally, the advent of new technologies and technological paradigms such as e-commerce, additive manufacturing, the Internet of Things (IoT) and radio frequency identification (RFID).

The combination of these four developments points to an urgent need to undertake actions that seek maximum performance in logistics activities taking place along the whole supply chain (production, transport, handling, storage, etc.) not only to eliminate waste or activities that do not add value (for example, by applying Kaizen or Lean Manufacturing approaches) but also to develop innovations in processes, products, and services.

At the same time, various stakeholders are showing increasing interest in developing sustainability (economic, environmental, and social) applied to supply chains, in line with the promotion of activities that foster the “Circular Economy.” Although a growing number of firms are backing the development of sustainable supply chains, most are still limiting themselves individually to meet legal commitments and sidestepping any “extended” responsibility they may have upstream or downstream along their supply chain. Nevertheless, different sources highlight an interest in developing sustainable supply chains given that they make it possible to save resources, reduce waste, and pollution levels, while at the same time providing competitive advantages.

In this context, packaging design is one of the key elements that can actively contribute toward improving the efficiency and sustainability of supply chains. Suitable packaging design can help eliminate “waste” such as unused storage, transport and sales points, difficulties in product handling, excessive use of materials, rejected products, and the loss of productivity in processes for packaging production, or product breakages and deterioration. What is more, packaging itself is a source of innovation in products, processes, and materials, which further strengthens its strategic contribution.

The packaging design process demands a holistic vision that allows efficient and sustainable alternatives to be sought. Well-known international firms, such as Ikea, Walmart, Procter & Gamble, Amazon, or Inditex, have turned their packaging into the cornerstone of their commercial and logistics strategies. However, the statement is not true just for firms operating in the consumer sector but also for those in the industrial sector. Proper integration of packaging design, product, and supply chain is the ultimate objective of “Packaging Logistics,” which this chapter deals with.

The chapter is structured into six sections, the first of which is this introduction. The following section details the different functional requirements associated with packaging design and how they are structured as a system. The third section covers the different assessment methods for packaging design alternatives, while the fourth deals with the different organizational connotations associated with the design process. The fifth section defines and reveals the “Packaging Logistics” approach and the chapter ends with a section giving some conclusions.

Design Requirements and the Packaging System

Before explaining the “Packaging Logistics” concept, it is necessary to know the different design functions or requirements that the packaging system must satisfy. Thus, beyond the traditional– and vital–function of protecting the products, the packaging must be designed, so that it not only has the capacity to differentiate the product commercially but also to provide production or logistics efficiency. That must all be done in a context in which sustainability is developed in its economic, environmental, and social dimensions.

Thus, the economic dimension could be analyzed from the different, and yet complementary, perspectives of income and expenditure. On the one hand, good packaging design can act as a “silent salesperson,” highlighting certain (tangible and intangible) features of products that increase their capacity to be different from others and surprise the market positively. On the other hand, suitable packaging can help reduce overall costs in the supply chain (particularly those for production and logistics), which is a critical aspect when it comes to conceptualizing and understanding the impact of certain design decisions. That impact, in terms of costs, will be dealt with in greater detail in the next section.

Regarding the environmental dimension of sustainability, packaging design also affects the amount of resources consumed. That consumption not only includes the materials used for the packaging, but also any other resources used along the supply chain, such as the fuel needed to transport the goods. Likewise, packaging design also affects the amount of waste and pollution produced. Logically, spoilt or damaged products caused by unsuitable packaging design have an equally important environmental impact.

Awareness and understanding of the environmental impact, particularly concerning waste and pollution, has led to the development of specific legislation, including European Directive 94/62/EC and its updates, which in practical terms has meant the promotion of the green dot for recycling and the adoption of specific mechanisms for managing packaging and its waste products (European Commission, 1994). That legislation, in line with growing public demands in environmental issues, establishes the prevention of waste generation as a conceptual priority, that is, the development of noncontaminating products and techniques in order to reduce any impact on the environment from the materials and substances used in packaging and present in its waste products during the production, commercialization, distribution, use, and elimination processes.

When this priority objective of impact prevention is not feasible, a second one seeks the use of any waste, starting with reuse of the packaging. If reuse is not an option, then recycling or adding value to the waste is the next ranked objective. Value is added by making the most of the resources contained in the waste packaging, including burning it for the energy it contains, so as to avoid any environmental impact resulting from the final treatment associated with its disposal, such as storing or dumping it in a controlled way or destroying it totally or partially by incineration or other methods that do not involve energy recovery.

In order to understand the impact that packaging waste has on the environment, it should be noted that it accounts for a third of all municipal solid waste. The European Commission estimated that in 2016, for each European citizen, 170 kg of packaging waste was generated (Eurostat, 2019), all of which not only needs managing at the end of its life cycle, but also means that there have been previous costs for the manufacturing firms in terms of raw materials, supplies, and so on.

Finally, packaging design also has an impact on sustainability's social dimension. This includes issues such as facilitating recycling schemes, supplying honest, understandable, and truthful information, guaranteeing safety when products are consumed, and adaptation of the product's use, ergonomics, and dose to the needs of different customers, such as senior citizens or people with disabilities.

On the basis of the above points on sustainability, the multi-dimensional impact and character of the design requirements that packaging must satisfy can be appreciated, along with the very different levels they exist on and needs they meet (Lindh et al., 2016). The different design requirements are summarized in Fig. 1. However, even though it is important to be aware of, and understand,

Figure 1 Packaging design requirements. Source: Own compilation and development

Figure 2 Structure of the packaging system. Source: Own compilation and development

the many varied design requirements that packaging is subject to, it is also necessary to know the structure of the packaging system itself, which typically has three levels: primary, secondary, and tertiary (Fig. 2).

"Primary" packaging is the product's first protector and is typically in contact with it; it is also known as the inner container, first container or consumer package. This level can simultaneously have various formats, materials and/or layers (e.g., a bottle in a cardboard box). "Secondary" packaging is designed to group several primary units of the same product or different products to provide protection and make handling easier during commercial distribution and sale. It is usually removed when the product is used or stored in the home. The common generic term is outer packaging or retail packaging. This level can also have several formats, materials, and/or layers (e.g., a cardboard tray and plastic film to group bottles of water or cartons of milk). Finally, "Tertiary" packaging is typically associated with several secondary units (of the same product or different products) which are grouped, for example, on a pallet or roll container to facilitate handling, storing, and transport tasks. This level is also called a unit load or transport packaging.

The fact that secondary and tertiary packaging can include one or more products is linked to the need to meet the needs of orders coming from firms, stores, or end customers (e.g., in e-commerce). Logically, given that these multi-product groupings usually diverge from the initial configuration established by the packaging company, additional handling activities are needed to prepare them and this will condition the efficiency and sustainability of the whole supply chain. Likewise, variables such as a product's size, its fragility, the number of units sold, and delivery frequency will also condition the design.

The three-level packaging system is applicable, conceptually, to all types of product, both in the consumer sector, where packaged products go to end customers, and in the industrial sector, where they go to be consumed and transformed by other firms. Clearly, if the supply chain changes, so will the design requirements. The interrelation between the three different levels of the packaging system (primary, secondary, and tertiary) should be coherent with the design requirements they are subject to. So, as there is a considerable dependency between the three levels in order to ensure that design requirements are met, adaptation to suit each level should not be evaluated separately, but rather in a joint and integrated way with the other two levels (Pålsson and Hellström, 2016). Furthermore, that integrated vision should be linked to the requirements and features of the product design and its associated supply chain.

So, for example, coordinated decisions about product, supply chain, and packaging can find a natural meeting point in the implementation of packaging postponement strategies. Such strategies pursue a reduction in the amount of stock of a certain product by delaying how it is specifically prepared for each customer. This aim is met by using a modular design for a product's

components and promoting flexibility in packaging processes. The more valuable a product is and the wider the range available, the greater the impact of packaging postponement will be.

Systems for Evaluating Design Alternatives

The business and academic literature highlights the lack of specific metrics for globally measuring and comparing the efficiency and sustainability of different packaging design alternatives. However, having a suitable evaluation system available for these alternatives is a critical factor when determining the most suitable design. It would thus seem reasonable to catalog the best packaging as that which simultaneously combines the most attractive and useful one for the customer (end or industrial) with the smallest overall cost, while at the same time generating the smallest impact on the environment (including the reduction in product losses and deterioration). As has already been mentioned, however, packaging is subject to a variety of design requirements. Logically, different metrics may exist that are linked to the application of each of those requirements. So, a suitable packaging design can highlight certain product features to increase its capacity to differentiate itself from others and, as a result, increase sales. In all events, sales are an after-the-fact indicator, as they measure suitability once new formats have already been implemented, which means that they are not the most reasonable way to approach the initial problem of measuring the pros and cons of each design alternative. One way of measuring this impact before a new format launch is based on techniques such as product, visibility, or stimulation tests “in the lab.” Likewise, those techniques can be complemented by using comparisons with competitors’ packaging (benchmarking), although the priority in this case is generally to study commercial aspects regarding the primary packaging.

At the same time, suitable packaging design can help reduce overall costs in the supply chain (**Table 1**). Cost reduction is an area where many firms find enough incentive to promote changes in their packaging. Regrettably, the relationship between those costs and any packaging design decisions is both direct—they show up directly in the firm’s accounts—and indirect, which means that the overall impact of certain designs does not always have “visibility.” This indirect relationship is what stops many firms from understanding the impact certain design packaging decisions have on the related costs. Furthermore, many firms do not even have reliable data and/or information to make the costs totally or partially visible or clear.

Nevertheless, when we attempt to measure the suitability of a certain packaging alternative from perspectives other than cost, the assessment or measurement system is not so clear and in many cases it is very difficult to fully convert them into economic

Table 1 List of potential costs affected either directly or indirectly by packaging design decisions in a retail supply chain

<i>Type of cost</i>	<i>Typical cost unit</i>	<i>Likely impact on the supply chain</i>	<i>Visibility of impact</i>
Raw materials supply	Purchase cost (including logistics costs linked to management, handling, storage, and transport)	Supplier and packer	Indirect
Purchase of packaging	Purchase costs (may or may not include supply cost)	Packaging manufacturer; Packer	Direct
Management, handling and storage of packaging	Cost per package (and/or grouping)	Packer	Indirect
Packing	Production cost (including costs for production management, machine preparation, packing process and rejects)	Packer	Indirect
Internal transport of finished product	Cost/pallet	Packer (between factories and warehouses; or to customers, if paid by packer)	Indirect
Internal handling, storage, and picking linked to finished product	Cost/pallet and/or cost/box (picking)	Packer’s warehouse	Indirect
External transport of finished product	Cost/pallet	Distributor (between packer and distributor’s warehouse when paid by distributor)	Indirect
External handling, storage, and picking linked to finished product	Cost/pallet and/or cost/box (picking)	Distributor’s warehouse	Indirect
Delivery transport	Cost/pallet	Distributor (from distributor’s warehouses to stores or sales points)	Indirect
Handling and storage at point of sale	Cost per pallet and/or cost per box	Stores or points of sale	Indirect
Environmental management of packaging waste	Cost per weight/volume depending on the material (may be linked to the green Dot cost)	Packer and distributor	Direct
Product losses due to inefficient packet and/or packing.	Cost of deteriorated returned products (including loss of product’s commercial value)	Any part of the supply chain (including stores and households)	Indirect

Source: Own compilation and development

terms. For example, whether packaging fulfills the protective function could be partially measured in economic terms by the cost of losses, deterioration, or returns. However, it would prove difficult to measure the dissatisfaction that these problems create in each section of the chain, particularly for the end user, as it is not necessarily reflected in sales (at least not immediately).

A similar difficulty emerges when trying to measure the environmental impact of the different packaging alternatives, because even though some of the effects can partially be measured in cost terms (e.g., waste management costs paid for by the Green Dot license fee), others are measured using scales that are not economic. For instance, the most widely-used system to measure environmental impact, "Life Cycle Assessment" (LCA), as embodied within ISO 14040:2006, is a technique that measures the carbon footprint generated not only by the packaging but also, more comprehensively, by the products throughout their life cycle (ISO, 2006).

With the rise of "ecodesign," the use of this technique has included different criteria and parameters for assessing environmental impact. A web-based platform used by firms such as Procter & Gamble, Johnson and Johnson and UPS, the COMPASS (Comparative Packaging Assessment) tool stands out among the more relevant initiatives which measure and compare packaging design from an environmental perspective and have the LCA technique in mind.

In all events, in the face of all the difficulties when objectively assessing each packaging alternative from a multifunctional perspective (i.e., not just environmental impact or cost) and under a global chain approach, different assessment models have been developed that combine quantitative and qualitative scales. By doing so, however, a certain degree of subjectivity is introduced into the results of any analysis. The most widely-used of these models is the Packaging Scorecard method (Olsmats and Dominic, 2003), popularized by firms such as IKEA. By analyzing cases of supply chains or specific packaging, they establish an assessment system for alternatives that combines the needs of each stage of the supply chain with specific qualitative and quantitative criteria.

Likewise, the literature includes other techniques and tools to deal with more specific aspects in the search for the best packaging design alternatives. Thus, measurement systems have been proposed that seek size optimization for boxes and/or volume optimization for packaging or loads. For the latter, there are IT design tools that prioritize the search for improvements in logistics efficiency (mainly to improve the occupied space in boxes, pallets, trucks and/or intermodal containers) by using different heuristic, metaheuristic, or integer programming techniques.

Finally, it is worth noting that over the last few years in the consumer sector, a set of IT tools has appeared aimed at managing more efficiently the space products take up on point-of-sale shelves. These shelf management programs not only look for the best physical use of the space, but also try to connect brand image and product categories (facings) with their economic sales performance by defining "planograms." Logically, these considerations on the rationalization of space at the point of sale are of little interest on purely electronic sales platforms.

Organizational Considerations in Packaging Design

After describing the design requirements, how the packaging system operates and the methods for measuring and assessing different alternatives, it is necessary to look at the structure of the design process itself, that is, delve into the organizational considerations. Logically, the variety of requirements demands a certain level of external and internal coordination in the design process. The importance placed upon each design requirement will depend on which area, department or firm within the supply chain is making the assessment. Furthermore, these design requirements are not evenly spread out over the various levels of the packaging system (primary, secondary, and tertiary), and neither are they to be found at each stage, process, or task within the chain.

At the same time, the final decisions affecting the three different levels of the packaging system could also be related to the part of the supply chain that is able to exercise greater influence or leadership. For example, if the distribution companies "dominate" over the packing firms (which is common place in the consumer sector, for example), the final decisions relating to packaging could be dependent on what the distributor considers a priority. Logically, this approach will not necessarily lead toward the best packaging solution from the perspective of the supply chain as a whole. Therefore, the organizational structure adopted should have the job of taking decisions about packaging design in a way that coordinates and seeks consensus among the affected parties, that is, the different areas or departments within each firm and the different firms within the supply chain (packaging manufacturers, packers, distributors, logistics operators, etc.). Likewise, it would be desirable for this organizational structure to be coordinated and integrated with those responsible for taking decisions about product design and about the supply chain. Conceptually, there are four ways to address this organization in order to face the structure of the design process as a whole (Olander-Roese and Nilsson, 2009):

- The basic or "traditional" approach. Packaging design is inefficient, starting during the last stages of development for a new product (and its associated supply chain).
- The "simultaneous" approach. Product design (and its associated supply chain) is developed at the same time as packaging design.
- The "static" approach. Packaging design is undertaken in a way that is integrated into the first stages of product design, but only the first versions. It is not then updated dynamically when the product and/or supply chain need changes in order to adapt to new design requirements and/or threats and opportunities in the environment.

- The “dynamic” approach. Packaging design leads and promotes the design of the product itself (and its associated supply chain), that is, the packaging provides the basis for innovative design of new products, updating its design in the face of changes in the requirements and/or threats and opportunities in the environment.

When the “dynamic” approach is used, there is not only a greater number of efficient and sustainable alternatives, but also feedback of coordinated criteria for selecting between them, creating a true driver for change and continuous improvement in the processes taking place throughout the supply chain. This is the approach put forward by “Packaging Logistics” which is explained in the next section. The design decisions that this organizational structure should be taking at a packaging level will be centered on five complementary and closely interconnected aspects:

- Selection of the materials to be used, including their type and quality.
- Selection of the technologies related to the processes in which the packaging will be involved. These technologies include, for example, those adopted in packaging processes or in handling, storing and transport, and will contemplate what level of automation to use. Likewise, identification technologies (such as RFID or barcodes) that enable tracing of the physical flow of products, in line with an approach linked to the IoT.
- The packaging’s esthetic design (shape, colors, text, symbols, images, etc.).
- Details of the structure in terms of levels and interconnections in the packaging system (primary, secondary, and tertiary).
- Selection of the dimensions used in the packaging.

Although all the decisions to be taken are relevant, the choice of dimensions is given here to illustrate the impact of such a selection in the areas of production, logistics, and the environment. In recent years there has been some standardization in dimensions, particularly for secondary packaging, where the use of 600 mm × 400 mm modules and its submultiples has been promoted in the ISO 3394:2012 standard (ISO, 2012). Implementing this standard facilitates the efficient use of some of the most commonly used pallets in the world (Fig. 3): the EUR (1200 mm × 800 mm) and the American (1200 mm × 1000 mm) pallets. Such standardization in packaging dimensions (for both the base and the height) also facilitates dimensional standardization to a large extent in resources used for handling, storing, and transport, which in turn facilitates the automation of some processes and, therefore, has an effect on logistics efficiency, and sustainability.

If standard format packaging is chosen, which has high efficiency in terms of logistics (palletizing) and production (reduced number of changes and adjustments in packaging processes), lower costs can be obtained. However, this approach may mean the sacrifice of some possible ways to differentiate the product. There are also questions to be asked about how product protection is ensured or how waste is minimized. Furthermore, in increasingly complex global supply chains, standardization (and automation) based on palletizing criteria can differ from those employed in courier systems or 20- or 40-foot intermodal containers. Couriers, often used by e-commerce, seek minimized size and weight and reduced risk of breakage, whereas intermodal containers, typically used in industrial logistics between manufacturers, do not efficiently fit pallets into the available space. Answers are also needed to the question of what dimensions to adopt when products with different packaging are mixed and efficient, sustainable deliveries must be still achieved along with the whole supply chain.

Looking in further depth at this issue, there are over 50 different cardboard boxes (typically used for secondary packaging) on the market. Fig. 4 shows one of the most widely-used types, which has overlapping lid flaps. For each target volume (V) there are an infinite number of alternatives combining different lengths, widths, and heights (shown as feasible alternatives on the graph). However, there is only one alternative for each volume V that optimizes the amount of cardboard needed (S) and the waste generated. The *blue line* on the graph shows this set of alternatives.

On a different note, throughout the course of structuring the process for product design, packaging, and supply chain, it can be useful to develop standards used for different management fields. The best known among these are quality management (e.g., the ISO 9000 standards) or environmental management (e.g., the ISO 14,000 standards). The literature particularly mentions the positive effect of these in terms of structuring and systemizing certain areas of management such as defining tasks, responsibilities, or deadlines. In packaging design, this positive effect could be associated, for example, with the documentation for the design process itself (for tasks, leaders, and deadlines) or recording technical, production, or logistics documentation associated with the process (e.g., technical sheets for purchasing and supply or palletizing forms).

Conceptualizing the “Packaging Logistics” Approach

Within the context described above of requirements, assessment systems and organizational considerations, the need arises to conceptualize the close relationship between the packaging design process, product design and supply chain (logistics) system design. This is the perfect scenario for developing the “packaging logistics” approach. A very early vision of the approach, still unnamed, dates back to academic circles in the 1990s, although it was very limited as it basically highlighted the relationship between physical distribution processes (handling, storage, and transport). The term used today was coined at the end of the 1990s in northern Europe, and was initially proposed as a structured relationship between the logistics system and the packaging system that would enable firms to improve profits (Björnemo et al., 2000). That notion was later developed and qualified as a more academic concept based on contributions from different authors, particularly from Lund University in

Figure 3 Efficient box dimensions for use on standard pallets under the 600*400 modular system. Source: Own compilation and development

Figure 4 Example of the search for dimension alternatives in box design Source: Own compilation and development

Sweden. However, this description should be considered as a first approach at a more complex definition, because even though it already highlighted the interaction between the logistics system and the packaging system, it oversimplified integration in the overall concept of the firm (rather than the supply chain) and sidestepped any relationship with product design.

Saghir (2002, p. 45) proposed a more integrated definition of the concept, “The process of planning, implementing, and controlling the coordinated packaging system of preparing goods for safe, secure, efficient and effective handling, transport, distribution, storage, retailing, consumption and recovery, reuse or disposal and related information combined with maximizing consumer value, sales and hence profit.” This definition now emphasized the active role of the packaging system in order to integrate different viewpoints at commercial, logistics and environmental levels and to affect the product system and the supply chain itself—with everything oriented toward improvement in the competitiveness of firms.

Later, García-Arca et al. (2014, p. 330), would adjust, qualify, and enlarge on the “packaging logistics” approach put forward by Saghir (2002) to include the context of sustainability, coining the term “Sustainable Packaging Logistics” (SPL), which they defined as: “The process of designing, implementing, and controlling the integrated packaging, product, and supply chain systems in order to prepare goods for safe, secure, efficient and effective handling, transport, distribution, storage, retailing, consumption, recovery, reuse or disposal, and related information, with a view to maximizing social and consumer value, sales, and profit from a sustainable perspective, and on a continuous adaptation basis.”

This new definition expressly mentions the processes involved, the sustainable sphere (social, economic, and environmental) and the dynamic vision of the five design decisions associated with packaging. As mentioned previously, this dynamic vision is critical, if the design requirements are to be adapted or fine-tuned to the threats and opportunities of their surroundings. Likewise, this definition reinforces the idea of integration of the three systems involved: packaging, product and the supply chain itself. Finally, it strengthens the idea of connecting packaging design with a firm’s competitive improvement, that is, obtaining better business results. In this context, there are three pillars supporting deployment of the “packaging logistics” approach in its broadest sense, that is, its contribution to deployment of the three areas of sustainability (economic, social, and environmental) (García-Arca et al., 2017):

- Definition of the design requirements, based on identification from a sustainable perspective of the overall needs of the different stages of the supply chain. The current level of competition in most markets would suggest integrating all these requirements without disregarding any of them in an attempt to achieve objective consensus that will satisfy all the priorities of the areas and firms along the whole supply chain.
- Definition of a system enabling measurement of the impact of certain design decisions (materials, technologies, levels structure, dimensions, and esthetics) on the efficiency and sustainability of the supply chain. This pillar is linked to the need to measure and compare costs, environmental impact and any other associated variable mentioned earlier in this chapter.
- Definition of an organizational structure to coordinate all the areas affected by packaging design along the whole supply chain, both internally—within each firm—and externally—between firms in the chain. This would mean integrating packaging design into the initial stages of product and logistics system design, and using a “dynamic” approach in order to adapt constantly not only to the different views and perceptions that each stage of the chain has of the design requirements, but also to the changes that can occur in the design requirements themselves and/or the environment. In practice, this would mean firms and supply chains learning and adapting efficiently and sustainably in packaging issues, that is, acting as “learning organizations.”

At the same time, the deployment of these three pillars would promote a culture of packaging-based change and continuous improvement in firms, which could be approached from different and yet complementary perspectives: on the one hand by adopting “management best practices” in the design process; and on the other by promoting changes and innovations in the packaging. The scope of best practice could include all those actions that pursue an efficient and integrated design process. This could include, for example, providing other parts of the chain with knowledge of logistics processes, documenting the design aspects (for instance, generating design procedures, technical instructions for materials, or palletization sheets), or using IT design tools to simplify decision-making.

The scope of change and innovation could include improvement guidelines that have already proved successful in other firms but which cannot be applied indiscriminately without prior knowledge of factors that condition the product, the other design requirements, and the supply chain itself. Logically, the field of innovations would include those provided by the dynamic packaging industry (e.g., in terms of materials, qualities, and packaging equipment or processes). Table 2 shows these possible changes or innovations and indicates the potential impact on overall costs.

Finally, in Fig. 5, there is a diagram of the authors’ management model for “packaging logistics” deployment. This diagram reflects the conceptual aspects mentioned throughout this section and uses a building as an analogy, in that, the more suitable the pillars of its structure become, the stronger it is able to function and propose and improve packaging alternatives, by taking the five associated decisions and growing and developing the three areas of sustainability (economic, social, and environmental). That is all done as an integrated part of the product and supply chain design.

Table 2 List of potential actions to improve packaging

Action	Main costs affected
Changes in packaging dimensions (primary, secondary and/or tertiary packaging)	Packaging purchasing costs Logistics costs (handling, storage and transport) Waste management costs
Change in the materials used in packaging (material type, quality, etc.) (including changes to improve the capacity to recycle or take advantage of the materials)	Packaging purchasing costs Waste management costs
Variation in the amount of product per primary packaging unit or the shape/size of the product	Packaging purchasing cost (per unit of product) Logistics cost (handling, storage and transport) (per unit of product) Waste management costs (per unit of product)
Change in the packing process (new equipment, new tools, etc.)	Packaging production cost Deterioration or reject costs
Change in the number of primary packaging units per secondary packaging unit	Packaging purchase cost (per unit of product) Logistics cost (handling, storage, and transport) (per unit of product) (includes handling at point of sale) Waste management costs (per unit of product)
Standardization in dimensions and formats for packaging	Packaging purchasing cost (economies of scale) Production cost (reduction in setup times)
Standardization in the qualities of the materials used in packaging	Packaging purchasing cost (economies of scale) Production cost (reduction in preparation times)
Elimination of "excess packaging"	Packaging purchasing cost Waste management costs Packaging purchasing cost
Change in the graphic art design or esthetics of the packaging (colors, texts, labels, shapes, etc.)	Packaging purchasing cost
Implementation of returnable packaging	Packaging purchasing cost Logistics cost (handling, storage, and transport; includes reverse logistics) Waste management costs
Implementation of SRP formats ("Shelf Ready Packaging")	Packaging purchasing cost (per unit of product) Packaging production cost Logistics cost (handling, storage, and transport) (per unit of product) (includes handling at point of sale) Waste management costs (per unit of product)
Rationalization of packaging and pallets for raw materials and components	Logistics cost associated with supplies (handling, storage and transport)

Conclusions

The implementation of the “packaging logistics” approach mentioned in this chapter should actively contribute to the competitive improvement of a supply chain and, by extension, to each and every firm within it. It is an implementation that will have been developed from a sustainable perspective.

Researchers can also find new lines for research in this chapter related to the role of packaging as a promoter of competitiveness for firms and supply chains within the contexts of sustainability (less consumption, waste, pollution, and losses), market globalization (including developing countries), commercialization channel diversity (including e-commerce and logistics flows between manufacturers) and new technologies in materials, processes, equipment, and traceability (IoT). Likewise, the way a design process is structured, in the pursuit of internal and external coordination in order to integrate design into a scope that encompasses product-packaging-supply chain, is another fascinating line for research that will require future study.

At the same time, practitioners can find in this chapter a structured methodological proposal for developing “packaging logistics” in their firms, based on the pillars of decisions and improvements that aim to obtain competitive advantages. The chapter not only explains how it is possible to align the “packaging logistics” approach with the strategy of firms, but also with that of their supply chains. After approaching the issue from the two standpoints of academic research and business practice, some final points are offered for reflection to arouse or encourage interest among professionals in businesses and research institutions when it comes to paying attention to packaging from a “packaging logistics” perspective:

- Suitable packaging design facilitates the capacity to make savings, improve sales, and operate in a more sustainable way.
- To obtain those results, it is necessary to identify the design requirements, measure, and compare alternatives from an all-encompassing perspective and strengthen collaboration and coordination between all the areas, departments, and firms in the supply chain.
- The more integrated the packaging, product, and design processes are, the more efficient and sustainable any adopted solutions will be.
- The selected alternatives for packaging should not be considered from a static standpoint, but from a dynamic one which is subject to potential changes and improvement.
- The final point for reflection is to point out that good packaging may not turn a bad product into a good one but, in almost all certainty, bad packaging will turn a good product into a bad one.

Biographies

Jesús García-Arca, PhD. He graduated in Industrial Engineering and is a Tenured Associate Professor at the Engineering School of the University of Vigo (Spain).

A. Trinidad González-Portela Garrido, PhD. She graduated in Business and Economic Sciences and Law and is a lecturer at the Engineering School of the University of Vigo.

J. Carlos Prado-Prado, PhD. He graduated in Industrial Engineering and is a Full Professor at the Engineering School of the University of Vigo.

They all have extensive experience in teaching, research and consultancy in the field of supply chain design, management and improvement, including efficient and sustainable packaging design.

Definition

The bullwhip effect is a supply chain phenomenon comprising two information distortion mechanisms. The first is that, for a given firm, the orders it places to its suppliers tend to be more variable than the demand it observes from its customers. This is called “demand distortion”. The second mechanism is the observation that demand distortion increases the further upstream a firm is in its supply chain (i.e., the further away it is from the final consumer). This is called “variance amplification.”

Due to the combined effects of demand distortion and variance amplification, a demand shock downstream generates demands that oscillate with increasing amplitude at each successive stage of the supply chain. This is said to resemble the visual effect of a bullwhip, with which a cattle farmer can use a flick of the wrist to break the sound barrier; hence the name. **Fig. 1** illustrates this resemblance, showing the evolution of demand on a stylized supply chain following a sudden, 2%, change in the end market.

Even though the term itself dates from the late 1990s (see [Lee et al., 1997a, 1997b](#), for the earliest appearances of the term), the mechanisms behind the bullwhip effect were first described in the late 1950s by Jay Forrester, a professor at Massachusetts Institute of Technology. Thus the bullwhip effect is also frequently referred to as the “Forrester effect,” named after his seminal initial work ([Forrester, 1961](#)). The bullwhip effect is often described in research through stylized models, typically using a nonstationary downstream demand stream (e.g., a sudden shock) as a trigger for instability. However, the bullwhip effect can also be observed under stationary demand.

One of the most significant contributions of the work of [Lee et al. \(1997a\)](#) was to show, mathematically, that the bullwhip effect could appear even under conditions of full rationality. Thus, while irrational behavior can increase its impact ([Croson and Donohue, 2006](#); [Sternan, 1989](#)), its appearance is not limited to improperly managed firms.

The bullwhip effect is undesirable because it generally increases operational costs and may cause further management problems in the supply chain, such as poor service levels. Demand distortion leads to inefficiencies in production and inventory management: highly variable production and/or inventories are required to serve highly variable (often oscillatory) customer demands. Therefore the bullwhip effect is directly responsible for costs associated with starting and stopping production equipment, successive idling and overtime periods, and/or workforce changes. Moreover, the bullwhip effect can also have a negative impact in ways that are difficult to quantify, such as difficulties in forecasting demand, and customer relations problems such as stockouts or delays in supply ([Disney et al., 2013](#)).

Because of variance amplification, the bullwhip effect is specially problematic for firms that are upstream in the supply chain. The compounding effect of variance amplification increases the impact of the bullwhip effect on firms located upstream within a supply chain; a chemical company, for instance, will typically suffer a larger bullwhip than a retailer. In fact, the inefficiencies associated with the progressive increase in upstream variability have a measurable effect on the relative production and inventory costs for upstream firms. Some studies estimate that these inefficiencies account for excess costs between 10% and 25% ([Lee et al., 1997a](#)).

From an information perspective, the importance of the bullwhip effect lies in the fact that it makes it increasingly difficult for firms to extract meaningful information from demand data. As one travels upstream in a supply chain, demand signals progressively diverge from the original consumer end-market demand. It is possible that after a few stages, very little resemblance remains ([Udenio et al., 2015](#)). Therefore, it is difficult for upstream firms to use their own demand signals to estimate consumer demand and to account for changes in the consumer market. In fact, most common examples and case studies based on the bullwhip effect illustrate this particular aspect; that is, how the production of diapers is more variable than what would be expected from the (relatively stable) usage by babies and toddlers, or how the DRAM market faces a much higher volatility than the computer market.

Figure 1 Illustration of variance amplification of demand on successive supply chain echelons.

This is of particular importance when consumer demand experiences a shock and when no information is shared among firms. In fact, minor consumer demand shocks result in upstream production levels that oscillate around consumer demand levels; making it impossible for upstream firms to link their demand observations with downstream market behavior merely based on the demand signal. This lack of visibility makes accounting for the bullwhip effect (i.e., taming the bullwhip) a difficult problem. Depending on the structure of the supply chain, downstream shocks can propagate and the related oscillations can persist for years.

In the academic literature, the bullwhip effect is classified in numerous ways. In this article, we analyze the bullwhip effect through three different theoretical causes. Namely, the bullwhip effect caused by delays within the supply chain structure (Forrester, 1961), the bullwhip effect caused by behavioral biases (Sterman, 1989), and the bullwhip effect caused by rational decision-making policies (Lee et al., 1997a). Whereas any one of the above is able to explain the appearance of the bullwhip effect, it is typical—in real life—to find more than one working concurrently.

The bullwhip effect is commonly introduced to students and executives in the classroom, using the “beer distribution game” developed by John Sterman. In the beer distribution game (see Sterman, 1989, for a detailed overview), four players (or eventually, groups of players) need to coordinate a supply chain, consisting of four echelons, without any interaction among the echelons being allowed. Commonly, this leads to excessive variance amplification over the course of the game. The bullwhip effect observed during a typical session of the beer game is caused by a combination of all the causes we discuss in this entry: the delay structure of the supply chain makes the oscillations all but inevitable, whereas the behavioral biases of the players, as well as a number of the structural causes, exacerbate the effect.

It is important to note that the bullwhip effect is at odds with the economic theory of production smoothing, whereupon production is kept constant in time and demand fluctuations are absorbed entirely through inventory (Abramovitz, 1950). The theoretical justification behind production smoothing is the assumption that changes in production output are generally more expensive than the necessary inventory buffers, thus it would be rational for firms to maintain production as stable as possible; allowing inventory levels to increase when sales decrease and vice versa. Successive steps of such countercyclical behavior implies that in a supply chain the variability of upstream demand would be lower than the variability of the end market.

Production smoothing was a common assumption in macroeconomic modeling until the 1980s. However, this modeling paradigm is difficult to justify empirically (Blinder and Maccini, 1991). At a macroeconomic level, inventory investment is strongly procyclical and, as discussed, production tends to be more variable than sales. To accommodate these observations, a number of economists have expanded the production smoothing model, noting that the addition of cost and/or productivity shocks can reconcile the model to observations. A different view in macroeconomic modeling eschews the production smoothing model altogether, arguing that avoiding stockouts is the more important metric for a firm, and that procyclical behavior and a production variability that is larger than demand variability (i.e., the bullwhip effect) follow naturally from this assumption (Kahn, 1992).

Causes of the Bullwhip Effect

The bullwhip effect was first analyzed in the late 1950s as a product of inventory and ordering policies and inherent delays in the supply chain structure. In the late 1980s, classroom experiments using the beer distribution game were conducted and human biases were introduced to extend the understanding and analysis. In the late 1990s, a more mathematically rigorous analysis of the bullwhip effect showed that supply chain decision-making, without the impact of delays or human biases, is enough to trigger the bullwhip. This triggered extensive research work encompassing more formal modeling, more empirical work at firm, supply chain, and industry sector levels, as well as more laboratory experiments detailing out earlier understanding.

Delay Structure

In the late 1950s, Jay Forrester introduced “industrial dynamics” (Forrester, 1961), and with it a new modeling paradigm for production and inventory systems. In this view, the defining factor causing the oscillatory dynamics typical of the bullwhip effect is the interaction of inventory policies and delays.

Delays induce the bullwhip effect because they disconnect decisions from the observation of their results. When there is a delay between making a decision and the observation of its result, then every subsequent decision must consider this delay and the associated uncertainty. Operationally, this implies keeping track of decisions taken but whose results are not yet observed and basing these decisions on expectations of future realizations. A typical example of a delay in a supply chain is the replenishment lead time; if the replenishment lead time is longer than the ordering frequency, then this delay forces the decision maker to keep track of multiple orders and to predict demand multiple periods ahead. Such delays complicate the analysis, noting that not all information in the supply chain can be observed and future demand is unknown.

Assuming there is a desired “end state” for a system, all decisions must be made as a function of this result. In practice, this implies that decision makers must decide, not only on desired inventory and production levels, but also on the path toward them. This is modeled through adjustment times; the desired amount of time that a decision maker wishes to spend chasing the desired state. Implicitly, this assumes a policy maker, and policy-related decisions. Such policies, the underlying behavior, and their effect on the bullwhip effect are explicitly modeled in the behavioral operations literature.

Behavioral Causes of the Bullwhip

Behavioral models of the bullwhip effect are commonly based upon the dynamic models introduced in [Forrester \(1961\)](#). Behavior is explicitly modeled through adjustment times—short adjustment times, implying “nervous” behavior, where quickly reaching the end state is prioritized at the expense of variability in orders/production; and long adjustment times as a way to model “relaxed” behavior, prioritizing stability over time to reach the desired state.

Behavioral models of the bullwhip effect are commonly investigated in experimental research, using the beer distribution game ([Croson and Donohue, 2006](#); [Sternan, 1989](#)). In this game four players assume different roles in a supply chain, from retailer to beer producer. In its basic form, no communication is allowed between players and an unknown consumer demand must be filled by the retailer, who can place orders to its supplier who, in turn, can place orders to its supplier, and so on, until the beer producer places manufacturing orders. The beer distribution game introduces information and material delays into the system, that is, it takes time for order information to travel upstream and it takes time for material (“beer”) to travel downstream. Analysis of data from the beer game shows that, in addition to the delays, behavioral attributes increase the magnitude of the bullwhip effect.

The main behavioral insight to come out from the beer game is that humans are not good at accounting for the pipeline (i.e., everything that has been ordered but not yet received). Compounded with long delays, this causes players to overreact to stockouts and order every period without taking into account outstanding orders. The effect of ignoring the pipeline is often seen as enormous oscillations; deep stockouts followed by equally large excess inventory. This effect is very robust and has been replicated innumerable times, in research as well as in the classroom ([Croson and Donohue, 2003](#); [Croson et al., 2014](#); [Narayanan and Moritz, 2015](#); [Moritz et al., 2019](#)).

Being based on the same paradigm as Forrester models, the underlying cause of the bullwhip effect in the beer game is the delay structure of the system. The insight from experimental research lies in identifying the behavioral biases present and how this irrational behavior further amplifies the bullwhip effect.

Rational Decision-Making Causes

Since the publication of the work by [Lee et al. \(1997a, 1997b\)](#), there has been significant interest in the theoretical mechanisms causing the bullwhip effect under fully rational decision makers. Under a periodic review inventory policy, for a firm calculating the optimal order quantity every period, the bullwhip effect appears due to four fundamental causes: demand signal processing, order batching, price fluctuations, and shortage games. These insights have been obtained using stylized analytical models.

- Demand signal processing: when a firm uses past demand information to forecast future demand, a nonstationary change in demand (e.g., a one-period surge or drop in demand) will trigger the bullwhip effect. In the absence of communication among firms, a supplier uses observed demand to update its forecasts. In such situations, nonstationary customer demands trigger changes in supplier forecasts that lead to increased variability due to a constant update of the optimal order quantity. The amplification of demand variability increases with the lead time, but it has been shown in an analytical model that amplification exists in this setting even when lead times are zero ([Lee et al., 1997a](#)).
- Order batching: if there is a nonzero ordering cost associated with placing an order, then order batching occurs naturally. If a supplier has a single customer, order batching implies that it will observe less frequent, larger orders, that is, increased variability. If a supplier has multiple customers, the impact of order batching depends on the correlation and timing of the individual demand streams. Under “perfectly synchronized” retailer ordering, that is, when a constant number of customers order every period, then the contribution of order batching to the bullwhip effect is avoided. In all other cases, order batching generates a bullwhip effect. Positively correlated ordering results in higher amplification than uncorrelated (i.e., random) ordering, which in turn results in higher amplification than balanced demands. Balanced demands are those, whereupon groups of customers place orders within a designated period every review cycle without any overlap (unlike perfectly balanced demands, the number of retailers placing orders in a given period is not constant).
- Price fluctuations: when a firm experiences variations in the purchase price, then it is optimal to adopt an ordering policy such that there exist different order-up-to levels, decreasing the purchase price. All else being equal, this results in increased variance of

orders and hence a bullwhip effect, compared to a policy with constant prices. As an example, consider a product with two prices, the regular price and a sale price. Unless the buying firm has full advance information on the sales periods, it follows logically that the optimal order-up-to level will increase whenever there is a sale and decrease when the price returns to normal.

- **Shortage gaming:** shortage gaming appears when a firm orders from a supplier that regularly suffers from stockouts. Facing a shortage, a supplier must allocate the available inventory among its customers. If such an allocation is (or is thought to be) proportional to the order size, customers have an incentive to inflate orders in an effort to obtain a larger share of the allocation. This sends a false demand signal that, interpreted by the supplier as a real increase in the demand, compounds the amplification problem (see demand signal processing). In addition, customers that inflate orders will typically cancel superfluous orders once the supplier catches up with demand; leading to a further increase in demand variability.

Measuring the Bullwhip Effect

The Bullwhip in Real Life—Anecdotal Evidence

Anecdotal evidence of the bullwhip effect abounds. In addition to the examples mentioned earlier, other famous cases are often used as case studies in business schools and the practitioner literature. Canned soup, dried pasta, and printer ink are some of the well-known examples of evidence of the bullwhip effect—products with stable consumer demand and highly variable upstream production. In recent decades, the bullwhip effect has become shorthand for the “inevitable” variability that upstream firms are required to contend with. Nevertheless, for all the usefulness of anecdotal evidence and case studies, rigorous research requires rigorous evidence of the existence of the bullwhip effect as a widespread phenomenon.

The Bullwhip in Real Life—Empirical Evidence

For all our understanding of the theoretical and behavioral causes of the bullwhip effect, extensive empirical research has been and is still conducted to show whether the bullwhip effect is an industry-wide problem, or if it only affects a limited number of individual firms. To this end, numerous researchers have attempted to rigorously measure it, using large panels of data. The evidence for the bullwhip effect in empirical data is not clear-cut (Bray and Mendelson, 2012; Cachon et al., 2007). There are a number of reasons that explain the nuances observed in the research.

First, empirical research, whether it uses primary or secondary data, typically uses aggregated data. It has been shown mathematically that measuring the bullwhip effect in aggregate data underestimates its impact (Chen and Lee, 2012). The particular degree of aggregation varies from study to study. Most empirical bullwhip effect studies use secondary data aggregated at the firm level with regards to products (i.e., all products are aggregated into a single stream), to inter-firm links (i.e., all customers/suppliers are aggregated into a single stream), as well as at the temporal level (observations are aggregated by month, quarter or even year) (Fransoo and Wouters, 2000).

Second, empirical research uses proxies to measure certain quantities. For example, sales data are used as a proxy of demand data and are combined with inventory data to estimate production data. In addition to the inherent errors that such estimations can introduce, the use of such data is conceptual at odds with the theory of the bullwhip effect. This is because the theoretical development of the bullwhip effect relies on the use of information flows in addition to material flows. As an example, the implicit assumption behind the modeling of the delay structure of a supply chain used in the beer game is that lead times are the result of a combination of the delay in information transmission (e.g., the time between placing an order and a supplier executing the necessary steps) and the material delay (e.g., the time it takes an order to be physically transported from a firm to its customer). Chen et al. (2016) show that using material flow data to estimate the bullwhip effect can over- or underestimate the real bullwhip effect, that is, the bullwhip effect as measured using information flow.

Another nuance that appears when measuring the bullwhip effect on empirical data is the stabilizing effect of demand seasonality. In real life, a significant number of products exhibit demand seasonality to a certain extent. For researchers estimating the bullwhip effect observed in the real data, the question is, then, whether this should be measured using the original demand stream or a deseasonalized demand stream (Cachon et al., 2007; Chen and Lee, 2012). From a theoretical perspective, including seasonality in the measurements can dampen the observed bullwhip; particularly if the variability of seasonality dominates the variability of the demand itself and, more so, if there are capacity constraints.

Of course, another source of ambiguity in the measured data is the fact that many firms actively seek to limit the bullwhip effect. Thus, in reality, there is a mix of bullwhip effect and production smoothing, and disentangling the one from the other is nontrivial.

Evidence from Macroeconomic Shocks

A number of studies took advantage of the 2008 credit crisis as a quasi-natural experiment, where the demand collapse in multiple industries approximated a nonstationary shock across entire industries. The evidence of an inventory shock is particularly strong. Such studies support the predictions regarding the transmission of the variability. In general upstream firms have observed more severe drops in demand than downstream firms. Moreover, recent studies claim that the inventory shocks by themselves,—that is, independent as a response to changing demand, but as a consequence of general financial or economic conditions—further amplify the bullwhip effect (Udenio et al., 2015).

Taming the Bullwhip

It is impossible to eliminate all structural and behavioral causes of the bullwhip effect from real life supply chains. Thus decision-makers can attempt to, at best, “tame” the bullwhip as much as possible. Ample research exists prescribing strategies to “tame” the bullwhip. Each of these strategies tackles one (or more) of the causes of the bullwhip effect highlighted earlier.

Delays in the supply chain structure amplify variability, thus minimizing delays is an obvious strategy to reduce amplification. Clearly, firms can only reduce delays by altering the structure of the supply chain in which they operate. All else being equal, a supply chain with short lead times will experience a smaller bullwhip effect than a supply chain with very long lead times. Firms willing to limit the appearance of the bullwhip are recommended, to the extent possible, to participate in agile supply chains; source (sell) from (to) suppliers (customers) with short lead-times. In practice, local supply chains are typically more agile than global supply chains. Note that the mode of transport used for deliveries affects lead times and thus the bullwhip effect. Thus such a strategic decision must consider the impact on variability amplification in addition to trade off between logistics costs, lead times, and environmental impact.

From a behavioral standpoint, the main recommendation is to avoid under-weighting the pipeline. While this recommendation directly addresses the main behavioral bias exhibited by human players of the beer game, research has shown that firms operating with policies that track “desired” inventory and pipeline targets (e.g., order-up-to policies) are also prone to under-weighting the pipeline (be it by design or through arbitrary adjustments). Furthermore, adopting fractional, rather than full, adjustments decreases the bullwhip effect generated by such policies. However, such fractional policies reduce the bullwhip at the expense of responsiveness to changes in demand (Disney et al., 2013).

Information sharing is often prescribed as a tool to counter the bullwhip effect because it tackles a number of structural issues. Under full information sharing, all firms in a supply chain can observe up-to-date inventory and/or demand information for all other firms in the supply chain. The visibility afforded by information sharing breaks the main mechanism behind the demand forecast updating; in this setting, firms can generate more reliable forecasts, for example by using downstream demand and inventory information to estimate future demand. This has been shown to be a particularly powerful action when combined with knowledge about the inventory policies that other firms employ. Directly sharing demand (and future order) forecasts among firms can similarly reduce the bullwhip effect.

In addition, information sharing can also mitigate the effect of shortage gaming, on the one hand by allowing suppliers to understand the “real” demand from customers (and thus avoid reacting to artificially inflated orders) and on the other hand by providing customers with information regarding the shortages that a supplier is facing. If a customer knows about the severity of a particular shortage, as well as the allocation mechanism and the expected recovery time, the incentive to artificially inflate orders to increase the allocation is greatly reduced. Full information sharing across a supply chain was previously considered all but unimplementable due to operational and technological barriers. Today, information sharing is starting to become technologically feasible. However, a strong barrier to its adoption is that, oftentimes, firms see demand and inventory information as a source of competitive advantage and thus classify it as sensitive and are not willing to share. Furthermore, the immediate benefits of information sharing are not symmetric. In fact, taming the bullwhip through information sharing requires downstream firms (the least affected by the bullwhip) to share information so that upstream firms reap the benefits. Downstream firms do not get comparable benefits from obtaining upstream demand/inventory information. Thus many downstream firms do not see this as a fair trade-off. However, this reasoning negates the second order benefits that downstream firms are able to obtain; if upstream companies achieve bullwhip reduction, then the decrease in inefficiencies and associated costs will sooner or later reach downstream firms in the form of lower costs, increased reliability and shorter lead times. Hence, information sharing typically needs to be associated with incentive alignment to be effective.

Other operational policies are designed to tame the bullwhip by attacking the root of each of the structural causes. For example, adopting “every day low prices” policies, or pricing contracts, to avoid the variability generated by price fluctuations; encouraging less-than-full truckload ordering via discounts and arrangements with 3PLs to discourage order batching; and adopting allocation rules that are independent of current orders (e.g., allocating based on past sales) to prevent rationing games.

Finally, there is the case for vertical integration. Information sharing is widely viewed as a way forward in regards to synchronizing the management of multiple firms and thus reducing the bullwhip effect. As discussed earlier, such implementations are relatively rare to find at large scale due to the view of information as competitive advantage. The vertical integration of firms enables what in practice is full information sharing of different stages of a supply chain, while at the same time avoiding competitive issues.

Glossary

A **block** is comprised of a group of transactions from the same time period, like a page from a record book.

A **blockchain** uses a special append-only data structure that are composed of transactions batched into blocks, which are cryptographically linked to each other to form a sequential, tamper-evident chain that determines the ordering of transactions in the system.

Consensus is the collaborative process that members of a distributed blockchain network use to agree that a transaction is valid and to keep the ledger consistently synchronized.

Merkle tree hashing is a computational function that ensures data blocks received from other peers in a distributed network are undamaged and unaltered.

A **miner** is a blockchain node that gets rewarded by some form of cryptocurrency or other incentives for creating blocks of validate transactions and including them in the blockchain.

A **hash** is a unique string of letters and numbers created from text using a mathematical formula. A hashing function turns any input (e.g., a password, or jpeg file) into a string of characters (i.e., a hash) that serves as a virtually unforgeable, unique, and encrypted digital fingerprint of the data.

A **node** is simply a computer on the blockchain network that stores the ledger.

A **timestamp** in a blockchain marks the time for each transaction on the blockchain proves when and what has happened on the blockchain and is tamper-proof.

Introduction

Widely recognized as one of the most disruptive technologies, blockchain technology has gained increasing popularity in recent years. Its core innovation lies in its ability to enable parties who are geographically distant or have no particular trust in each other to record, trace, monitor, and transact assets (tangible, intangible, or digital) without the need for third party verification. It therefore powers a range of innovative products, tools, and concepts such as cryptocurrency (e.g., Bitcoin or Ether), digital identity, and smart contacts and leads to new business and economic models.

Blockchain is a shared, distributed electronic ledger technology that can record transactions as they occur between parties in a secure and tamper-resistant way. Transactions in a blockchain are typically confirmed by all participants via a consensus mechanism and are not subject to any form of central control. Once validated and recorded in a blockchain, a transaction becomes permanent. An identical copy of the ledger is thus held by all users (known as nodes) on the network. No single party is able to delete or change a transaction unilaterally. Hence it is resistant to unauthorized change or malicious tampering, as participants in a blockchain network will immediately spot a change to one part of the ledger.

Blockchain and distributed ledger technology (DLT) are often used interchangeably. But strictly speaking, blockchain is an architectural subset of DLT. A critical difference between a distributed ledger and blockchain is that a distributed ledger does not have to consist of blocks of transactions to keep the ledger growing. The blockchain technology was invented by someone using the name

Satoshi Nakamoto in 2008 and is an innovative combination of a few existing technologies such as distributed ledgers, cryptographic protocols, and consensus mechanisms.

How Does It Work?

Let us assume that a transaction between two parties (from A to B) needs to be initiated. A transaction in this exchange could represent money, contracts, deeds, medical records, or any other asset that can be described in digital form. As shown in Fig. 1, Party A starts the transaction by first creating and then digitally signing it with its private key. The transaction is then propagated to peers (i.e., other nodes) of the blockchain network, which validate the transaction based on preset criteria. Once the transaction is validated by peers, it is combined together with transactions to create a new block of data for the ledger. The new block is then added to the existing blockchain and becomes part of the ledger. The transaction is complete and becomes permanent. In a blockchain, the blocks that contain batches of transactions are mathematically “chained” together in a chronological order (a term known as “time stamping”) using cryptographic techniques, hence the name “blockchain.”

The network participants in a blockchain use a consensus mechanism to eliminate the need to rely on central or third parties to validate transactions, and to ensure the single version of truth for all. Consensus mechanisms vary based on the type of blockchains

Figure 1 How blockchain works. Source: https://kilroyblockchain.com/skin/frontend/kilroy/default/images/how_does_blockchain_work.png, free to modify, share and use).

discussed earlier. For example, Proof of Work (PoW) is the most popular mechanism used in public blockchains, where miners must solve complex mathematical problems to verify transactions (a process known as mining). A reward is given to the first miner who finds the solution. Another popular mechanism is Proof of Stake (PoS), which tends to be deployed in a permissioned blockchain. PoS replace miners with validators where they will lock up some of their deposit (e.g., in terms of cryptocurrency) as a stake, and a group of validators takes turns proposing and voting on the next block and the weight of each validator's vote depends on the size of its stake. The validator collects network fees as the reward. Both PoW and PoS have their pros and cons. The former scales well, but is often criticized for its heavy time and computing power consumption, while the latter is more energy efficient but does not scale well. Currently, there are active efforts from industry and academia trying to find the right balance between scalability and performance and as a result a plethora of consensus mechanisms have been proposed, for instance Delegated Proof of Stake, Proof of Elapsed Time, Proof of Importance, and Proof of Activity, to name only a few.

Types of Blockchain

Due to its embryotic state, there is currently no agreement on blockchain categorization. A general approach is to distinguish the type of blockchain based on its access control, that is, who can read and submit transactions to a blockchain and participate within the consensus process.

If a blockchain is open to all, whereby transactions can be validated by anyone, then it is considered as a permissionless (sometimes also known as public) blockchain. Earlier versions of blockchain are permissionless; transactions are broadcast to every single participant (node); and every node thus keeps a complete record of the entire transaction history. Economic incentives are built in to encourage honest behavior, for example, rewarding miners with tokens. Bitcoin is a typical example of a permissionless blockchain.

Later, organizations realized that due to the sensitive nature of their data and regulatory concerns, sometimes a public blockchain was not a feasible option. As a result, permissioned (also known as private) blockchains (where only authorized participants can join) emerged to adapt to the needs of those organizations. Most blockchain technology networks observed so far in logistics, and supply chains are permissioned-based—where transactions and transaction-related data are only broadcast to selected parties (those involved in a specific trade to which these transactions relate). As a result, each node only holds records of which it is involved with. A few consortia-based initiatives in industry, such as the one led by Walmart and IBM on product provenance can be considered as permissioned blockchains because only related supply chain actors will be participating in this blockchain.

In practice, there is a broad spectrum of distributed ledger models, with different degrees of centralization and different types of access control to suit different purposes. Other terms such as hybrid blockchain (which allows participants to use permissioned networks that limit access to some data while also interacting with any public blockchain when needed) have also emerged. Over time, more blockchain variations have been added, such as public permissioned blockchain, federated, or consortium blockchains. The blockchain landscape is far from being settled.

Why Blockchain in Logistics

Therefore does blockchain matter to logistics and supply chains? Before offering a quick answer, we need to examine the unique attributes of blockchain technology and the core innovations that it entails.

- **Disintermediation:** blockchain's peer-to-peer network reduces reliance on any third party. Network participants can independently verify the integrity of the shared database and have a shared control over the entire database. Thus the integrity of data is guaranteed by a whole network, not by an intermediary. This opens up a number of opportunities for supply chain actors. For example, with blockchain, interfirm payments or digital assets transfer can occur without the authentication of a third party. Disintermediation will likely take place if the cost of existing supply chain intermediaries exceeds the value they add. New intermediaries that offer blockchain related products and service may emerge to facilitate blockchain's further diffusion along the supply chain.
- **Transparency with pseudonymity:** the information within a blockchain is visible to all participants and cannot be altered by a single entity, thus this improves auditability, creates trust, and reduces fraudulent behavior. Users can remain anonymous or reveal their identity to others. The extended transparency and traceability is seen as being of great value for industries that are sensitive to products and materials provenance. For instance, the blockchain could be used to trace the origin and production process of food ingredients, to detect fake products in a pharmaceutical supply chain, to assist the management of the whole product lifecycle in the automotive sector and support agile responses in the process of product recalls. Blockchain can be useful in supply chains where there is a need to minimize the degree of trust required between participants, or reliance on an intermediary service provider.

Given that the trust has been "programmed" into a blockchain through cryptography, relational investment is not as essential as in traditional supply chains (a costly, time consuming process). This may support the provision of a more agile type of logistics and supply chain operation, which is only configured temporarily to fulfil a particular demand and later could evolve and dissolve when conditions change.

- **Immutability:** once data are appended to a block and these blocks are collected in a chain, they cannot be changed or deleted by a single actor. Instead, they are verified and managed using governance protocols. This set up can effectively secure the data in blockchain ledgers against unauthorized access or manipulation. This is an important advancement, as any falsification of the information has to be done in real time, making it much harder than simply substituting new data. Therefore blockchain could be used as a registry and inventory system for recording, tracing, monitoring, and transacting tangible or intangible or digital assets. Caution though as absolute immutability does not exist. Reverse transaction, in theory, can be implemented if enough nodes (i.e., 51% or more) decide to collude.
- **Security:** cryptographic techniques, including cryptographic one-way hash functions, Merkle trees, and digital signatures, are deployed to safeguard the records in the database. Logistics and supply chain actors can encrypt and protect sensitive and commercial information and use business rules to control access by related parties, such as customs. Unlike a centralized system, if a system is hacked or there is some technical malfunction, the whole system may be brought to a halt, since the blockchain, by design, has no single point of attack and failure and can be more resilient to cyber hacks.
- **Automation:** blockchains can be programmed to automate a large number of business processes across different entities (e.g., make a payment) once certain conditions are met. Part of blockchain's novelty lies in its ability to set rules about a transaction (business logic) that are tied to the transaction itself. This contrasts with conventional databases in which rules are often set across the entire database level or in the application, but not in the transaction. This function supports the much discussed concept of a smart contract, whereby a smart contract is a computerized transaction protocol that automatically executes the terms of a contract upon a blockchain. Smart contracts are believed to be able to satisfy common contractual conditions, while reducing the costs and delays associated with traditional contracts. For example, a smart contract might send a payment to a supplier as soon as a shipment is received by the buyer. A smart contract, thus, eliminates payment withheld issues and improves efficiency by eliminating contract registration, monitoring, and updating efforts and time.

Blockchain Use Cases in Logistics

As blockchain technology matures, there are active efforts from almost every industry, as well as public and third sectors, in exploring how to capture the new opportunities afforded by blockchain. The following outlines some of the most popular use cases observed in the area of logistics and supply chain management.

Product Provenance and Traceability

A blockchain system offers extended visibility among multiple supply chain actors of a (digitized) product's digital footprint, from manufacturing to distribution and sale, thus creating so-called "see-through" supply chains. The immutability afforded by a blockchain system enhances data integrity and leads to increased confidence from customers of a product's legitimacy. Moreover, the use of timestamping (the process of providing a temporal order among sets of events) in the blockchain can prove the existence of certain data at a point of time, avoiding potential conflicts and disputes between parties over time-sensitive issues. Information completeness can be enhanced as well, as blockchain can accommodate a wide range of data, including ownership, location, product specification, and cost.

There is currently a strong industrial appetite in using blockchain for product provenance, in order to respond to the increasing demand from customers for the proof of legitimacy and authenticity of the products they purchase. Products range from luxury items (e.g., diamonds, watches), pharmaceutical products, aerospace, and automotive parts to organic and fair-trade food products. Therefore it is not surprising to observe that crucial supply chains are currently paving the way of blockchain deployment, where offering extended visibility is seen as a strategic value adding activity to multiple stakeholders.

Product provenance and enhanced traceability do not only deliver commercial benefits but are also of critical importance for product safety and quality assurance. It allows companies a quick response to product recalls and other safety-related issues. For instance, Walmart announced in September 2018 that it required all of its leafy green vegetable suppliers to submit and upload data to its blockchain tracking system by end of September 2019. This initiative is a direct response to the two Romaine Lettuce E. Coli Outbreaks in the United States in 2018, which caused over 200 people to fall sick and left 5 dead. Blockchains can also play an important role in stolen merchandise recovery, and in detecting counterfeit products and fraudulent transactions.

There are also emerging efforts in the blockchain's convergence with other technologies, such as Internet of Things (IoT), for real-time product tracking and whole life cycle asset management. This has important implications for asset-intensive industries, such as power, oil and gas, telecommunications, automotive, transportation, and construction, where asset management is critical to risk management and operational efficiency. Life cycle asset management also powers the concept of the circular economy and enables the reuse and recycling of materials (e.g., steel, batteries) back to the supply chain. The integrative use of artificial intelligence with blockchain for autonomous analysis and decision making is another area that attracts increasing attention.

Process and Operations Improvement

Implementing blockchains could improve efficiency in logistics and supply chains because the technology streamlines the data transfer between parties and thus reduces the time products spend in the transit process, improves inventory management, and ultimately reduces waste and cost. In a supply chain ecosystem, there are numerous bilateral transactions between organizations, creating many data silos and multiple versions of “truth.” Processes tend to be fragmented and, in some cases, largely manual and complex.

A blockchain platform can help to ease the current heavy workload on information transfer and processing, and bring multiple stakeholders together by the digitalization of document transfers and the acceleration of the flow of data. Fig. 2 shows the current state (A) and future (B) blockchain enabled information exchange process in a cross-border logistics and supply chain context. In a blockchain enabled cross-border system, data and digitized critical documents, such as a Bill of Lading, are appended by related parties into the blockchain along the progress. Customs clearance has been seen as a major bottleneck in a cross-border supply chain. The system will provide real-time visibility into the cargo status, therefore significantly improving the information available for customs authorities to inspect cargo, make decisions, and conduct risk analysis. The real-time end-to-end visibility also affords shippers, consignees, freight forwarders, port operators, and carriers greater predictability, earlier notification of issues and full transparency to validate fees and surcharges.

International payment requires a series of intermediaries for both clearing and settlement, and is complicated and expensive. A blockchain system can facilitate the business-to-business settlement at a fraction of the cost and time of traditional correspondent banking. A Deloitte report in 2016 has claimed that cross-border payment on blockchain has resulted in a reduction of transaction time from 2 to 3 days to a few seconds, and a 40%–80% reduction in transaction cost. Therefore cost savings can be substantial for organizations that make frequent international transactions. The added transparency and security can eliminate the risk of discrepancies in record keeping and safeguard the cash flows in a global supply chain. For cross-border settlement between two

Figure 2 (A) Current state: cross border logistics and supply chain information exchange. (B) Future state: a blockchain enabled cross border logistics and supply chain information exchange. Source: Yingli Wang.

financial institutions, it would normally require that two parties agree together to use a stable coin (a cryptocurrency which is pegged to an asset with a stable value, such as gold or fiat money), central bank digital currency or other digital asset as the bridge asset between any two fiat currencies. The digital asset facilitates the trade and supplies of important settlement instructions. Cross-border payment is an important area where blockchain solutions have been developed and deployed commercially.

Automation and Smart Contract

Current operations, processes, and data exchange in logistics and supply chains are often manual, slow, and error-prone. With smart contracts, blockchain technology allows for increased automation and efficiency through avoiding the rekeying of data, speeding up of transactions and reduction of errors. In the blockchain context, a smart contract is a computer code running on top of a blockchain, containing a set of rules under which the parties to that smart contract agree to interact with each other. If and when the predefined rules are met, the agreement is automatically enforced. The smart contract code facilitates, verifies, and enforces the negotiation or performance of an agreement or transaction.

Smart contracts can potentially help with the cascading of purchasing orders, invoices, change orders, receipts, ship notifications, other trade-related documents, and inventory data across a supply chain. The automation of contractual terms in traditional database architectures is known as “stored procedures”. The key differences of running a smart contract in a blockchain context lies in the fact that smart contracts are guaranteed by system rules and the outcome is verifiable and auditable by all network participants. For example, a smart contract might send a payment to a supplier as soon as a shipment is received by the buyer. A GPS-tracked product return could log its location in real time and trigger a signal within the blockchain for immediate refunds.

Blockchain may also be utilized to support machine-to-machine payment in the IoT context. For instance, IOTA is currently developing an alternative DLT application named Tangle that is designed specifically for micro transactions between IoTs. A potential use scenario is that autonomous vehicles—such as forklifts, trucks, or any industrial machine—could pay for their own energy or fuel, maintenance, and insurance. Taking an example of a smart charging station for an electric vehicle, an electric vehicle plugs itself into a charging station. Both the vehicle and the charging station are equipped with their own digital wallet. A smart meter tracks usage for calculating payment. Payments (e.g., using a cryptocurrency) between the two wallets take place automatically after the vehicle is fully charged. The same concept could be applied to toll and parking payments. A smart contract, thus, eliminates payment withheld issues and improves efficiency by eliminating contract registration, monitoring, and updating efforts and time.

Trade Finance and Settlement

Blockchain used in trade finance mainly focuses on removing inefficiencies from existing processes. For example, blockchain can be used for faster credit risk assessment, minimized human errors in documentation checks, instant verification and reconciliation of records, automatic execution of workflow steps via smart contract and instant and secure exchange of data.

Crowdsourcing is another area of application. A blockchain-enabled finance platform could help to widen access to capital. This will be of particular benefit to micro-, small-, and medium-sized businesses (SMEs), which tend to have more difficulties getting loans from banks, due to their limited credit ratings. A blockchain platform would allow a micro or SME organization to source from a wider group of stakeholders, for example from a large number of investors with very small amounts of capital. Therefore, access and entry requirements are democratized.

Another application is the tokenization of existing assets (e.g., physical items) in supply chains. Tokenization refers to the process of digitally representing an existing, off-chain asset on a distributed ledger. In a blockchain network, cryptotokens can be created to denote custody or ownership of the bearer. By tokenizing the trade asset, its transfer between transaction participants on the blockchain network mirrors the movement of the physical asset, tracking the change of ownership and supporting product the traceability and provenance discussed earlier.

Finally, a token could be a native currency in a permissioned, blockchain-enabled supply chain system to facilitate fast and secure financial transactions between community members. This could reduce the high transaction cost associated with traditional finance and may help to reduce currency exchange volatility for cross-border transactions (see previous discussion on international payment in the Process and Operations Improvement section). In this case, tokens tend to link to national currencies. As a result, a price can be established for these tokens, and they become digital assets that have a certain value.

Anticorruption and Humanitarian Logistics

In a blockchain, unethical or opportunistic behaviors are made visible to all participants. This level of transparency can be of great value to traditional supply chains, such as in pharmaceuticals, where dominant supply chain actors may manipulate the market to inflate product prices; or in coffee supply chains where a fairer payment to farmers can be made visible to relevant stakeholders. Similarly, a blockchain system could help to expose and eliminate the corruption that is witnessed in certain public–private interactions. In a similar vein, blockchain has been deployed in humanitarian supply chains to ensure that financial or other emergency aid reaches the target beneficiaries.

For example, the World Food Programme (WFP)’s Building Blocks pilot project uses an ethereum-based blockchain technology to make the delivery of funds more efficient and secure to help refugees of the Syrian Civil War. In the Azraq refugee camp in Jordan,

10,000 people receive food from entitlements recorded on a blockchain-based computing platform. Refugees purchase food from local supermarkets in the camp by using an eye scan instead of cash, vouchers, or ecards. The blockchain allows the WFP to account for balances without the need for a third-party financial service provider to act as an intermediary. The major benefits include the large reduction of payment to financial service firms, increased privacy for beneficiaries and quicker reconciliation of accounts.

Conclusions

Despite the great potential of blockchain for logistics and supply chain applications, its deployment is not without challenges. Blockchain deployment implies significant technological (e.g., security), legal (enforcement mechanism when disputes arise), and societal (e.g., removal of intermediaries and potential job losses) implications. The adoption of blockchain in logistics and supply chains imposes some fundamental changes in relational, structural, process, and technological configurations between multiple parties in the ecosystem. There are a number of issues that have been raised in practice concerning its further diffusion:

- Confidence and related necessity issues—block chain's infancy state, lack of demonstrable benefits at scale, lack of expertise and knowledge in organizations;
- Cultural, governance, and collaboration issues—traditional mind-set, complex multiple-stakeholder involvement, conflicts in interests and objectives, and lack of clarity on roles and responsibilities;
- Technical issues—data integrity, interoperability and standards, data ownership, information sharing and scalability, and performance trade-offs; and
- Cost, privacy, legal, and security issues—relatively high deployment cost, commercially sensitive information and privacy, regulatory uncertainties.

Despite the aforementioned challenges, it can be observed that blockchain developments have gradually shifted from the pilot and proof of concept stage to larger scale deployments. Most efforts in logistics and supply chain currently concentrate on the building of permissioned, purpose-built platforms. Lessons and best practices learnt from those early efforts indicate that for any blockchain projects to succeed, the starting point is to identify areas where there are pertinent problems in an existing supply chain that blockchain technology would help address. This requires a clear purpose and business case to be established. The core value of a blockchain system is in its shared, append-only, distributed ledger across a network of organizations. If the problem is organizational rather than interorganizational, the blockchain may not be the right technological solution. However, that said, blockchain can be used as an enterprise solution for large organizations that have multiple divisions across the globe, where it can facilitate interdivision transactions within the organization.

Once a business case is identified, the next stage is to build a blockchain ecosystem by deciding on participating organizations. In practice, a small group of consortia tends to be set up and act as the founding members of a blockchain ecosystem. This small community tends to be led by an influential supply chain actor (e.g., a large retailer, a shipping line or a port operator), which has sufficient power to pull and push other community members toward the execution of a project goal. The blockchain platform value needs to be clearly articulated, which will then dictate its core activities and processes. The value proposition also largely influences the choice of application solutions, for instance whether to build in house or purchase propriety solutions or deploy blockchain as a service model. It is critical to set up a proper governance and legal framework within the community that defines the ways by which the participants access or exit a blockchain network; the types of roles each member will play; and the ways to resolve potential disputes among members. Once the pilot is completed, the organizations can then start to explore how to scale up.

There will not be a one-size-fits-all approach when it comes to blockchain deployment. Blockchain technology can be utilized along, or better still, combined with other digital technologies to offer innovative products and services that otherwise would not be available in the marketplace. Given the rapid changing landscape of blockchain and DLT, both industry and academia need to keep abreast of its development, understand the potential areas where it brings value, and prepare for its disruptive effect.

Introduction

Asia is the Earth's largest and most populous continent, covering an area of 44,579,000 square kilometers (17,212,000 square miles), about 30% of Earth's total land area and constituting 4.5 billion people (as of September 2018), roughly 60% of the world's population. There are more than 50 political entities in Asia, most of which are members of the United Nations.

Asia has the largest economy of any continent, both by nominal gross domestic product (GDP) and PPP, and is the fastest growing economic region. As in all regions of the world, the wealth of Asia differs widely between, and within, states. This is due to its vast size, meaning a huge range of different cultures, environments, historical ties, and government systems are represented. The largest economies in Asia in terms of nominal GDP are China, Japan, India, South Korea, Indonesia, Philippines, Thailand, Taiwan, United Arab Emirates, Iran, Malaysia, and Singapore.

As is shown in **Table 1**, there exists a disproportionate relationship among GDP, population size, and area coverage for subregions in Asia. The top 16 economies in terms of GDP, representing about one-third of Asia's economies (16/48), create more than 90% of Asia's GDP, revealing that only one-third of Asian economies dominate the wealth in Asia. Though not the largest subregion in terms of population and area, East Asia, with China and Japan as the representative economic powerhouses, is adjacent to the Pacific Ocean and has a major trade interaction with North America. East Asia is also the largest economic power in Asia, holding over 65% of the total GDP in Asia. In contrast, Central Asia falls within a landlocked area with the least population size and the poorest economic performance in Asia, with less than a 1% share in Asia's GDP. Thus, in the last 20 years, East Asia has been the most vibrant and innovative Asian subregion involved in global economic and logistics development, while Central Asia has seen the opposite.

In recent years, Southeast Asia and South Asia (mainly India) have experienced strong economic growth due to a more open trade environment, low cost production factors, and the trade war between the United States and China. These regions have attracted a great deal of foreign direct investment (FDI) from global firms wishing to build their new manufacturing base. Furthermore, a burgeoning middle class in these regions has created greater demand for consumer goods of all kinds which, in turn, creates greater demand for not only trade logistics but also domestic logistics and distribution within the region. This trend has also altered the inter- and intra-regional trade logistics landscape in recent years.

There have been wars in different parts of Asia due to religious conflicts and the fight against terrorism. In particular, there have been civil wars in West Asia and South Asia. These wars have increased in intensity since the US 911 terrorist event in 2001. Therefore, the ongoing military actions in these two Asian subregions have raised a great demand for military logistics and weapon shipments. However, the wars and military actions have also created many refugees that are fleeing away from the war zones and looking for shelter in neighboring countries or even distant promised lands without war zones. Thus, there has been a great need for humanitarian logistics implemented, in particular, by the United Nations and international relief organizations. Increasingly devastating natural disasters, largely linked to climate change, such as the 311 earthquake and the tsunami in Japan causing the Fukushima Nuclear Plant Disaster in 2011 have brought great damage to life and economies, as well as tremendous challenges for disaster relief operations and logistics.

In brief, it is a highly challenging task to write an article about logistics in Asia since Asia is such a diversified and fragmented region with so many different geopolitical, economic, and natural influences on the demand for different logistics solutions for many varied stakeholders, with sometimes similar, but sometimes conflicting, interests. Thus, this article will focus solely on providing an overview of the economic and trade aspects of Asian logistics development.

Table 1 A regional view of Asia's scale in the global economy

Region	Economy count	GDP nominal (2018)		Population (2016)		Area coverage	
		\$ M	%	Size	%	km ²	%
Asia ^a	48	29,734,672	100.00%	4,535,326,831	100.00%	48,261,992	100.00%

Asian Logistics Within the Global Economy

Asia differs very widely among and within its subregions with regard to ethnic groups, cultures, environments, economics, historical ties, and government systems. With approximately 4.5 billion people, Asia hosts 60% of the world's population and continues to experience high growth rates in both population and economy. Over the last 3 decades, Asia's economic development and integration into the global economy has, arguably, been the most intriguing commercial story on the planet. However, due to its diversity and associated complexity, Asia continues to be the most disconnected region in the world. Therefore, it is fascinating as well as challenging to uncover the critical issues and theories relating to Asian logistics development.

Evolution

The integration of national economies into a global economic system has been one of the most important developments of the last century. This process of integration, often called "globalization," has materialized in the form of a remarkable growth in trade between countries. Exports today are more than 4000 times larger than in 1913. Up to 1870, the sum of worldwide exports accounted for less than 10% of global output. Today, the value of exported goods around the world is more than 25%. This shows that over the last hundred years of economic growth, there has been an exponential growth in global trade. This development has also created huge demands on both goods and service logistics flows either globally, regionally, or domestically.

Asia first emerged as a manufacturing power in the 1960s, when Japan began exporting electronics and consumer goods. Taiwan and South Korea followed its lead. By the 1980s, Japanese firms were building plants across Southeast Asia. But China's opening up was the game changer. In 1990, Asia accounted for 26.5% of global manufacturing output. By 2018, this had surpassed 50%. China accounts for half of Asia's output today. The region's share of the global trade in intermediate inputs—the goods that are eventually pieced together into final products—rose from 14% in 2000 to more than 50% in 2018.

Trade transactions include both goods (tangible products that are physically shipped) and services (intangible commodities, such as tourism and financial services). The production chains for these goods and services are becoming increasingly complex and global. In today's global economic system, countries exchange not only final products, but also intermediate inputs. This creates an intricate network of economic interactions that cover the whole world. According to recent estimates, about 30% of the value of global exports come from foreign inputs. Under this trend, intra-industry trade, that is, the exchange of similar products belonging to the same industry, has grown substantially to alter the traditional export–import logistics flow between two countries under inter-industry trade to an intricately intertwined global supply chain network. Recent years have seen a trend in international trade called splitting up the value chain. The value chain describes how a good is produced in stages in multiple countries. The production and distribution of the iPhone, for example, involves the design and engineering of the phone in the United States, parts supplied from Korea, Japan, Taiwan, and many others, the assembly of the parts in China, and the advertising and marketing done in the United States and many consumption countries.

The success of Factory Asia over the last 2 decades is a sign that Asian countries have been able to put business ties above political disputes. Commerce has brought them closer together. ASEAN nations have a free-trade agreement, with China. Japan, China, and South Korea negotiate a deal among themselves. There are also talks, still early, about a broader pact that would tie all countries in the region together, including India. Countries with lots of cheap workers should produce labor-intensive goods; rich countries should focus on those requiring plenty of capital. Richard Baldwin, an economist, argues that simply comparing national advantages is outdated. As supply chains spread across borders, regional comparative advantage matters even more. With its bounty of both labor and capital, Asia has already built up a huge lead in manufacturing. It only stands to grow.

Since 2018, world trade has run into a strong headwind due to trade imbalances and the resulting economic power shift between the West and the East causing the trade war between the world's two largest economies, the United States and China. This will

certainly affect how global firms adjust their supply chains. However, it will not deter the development of already highly connected and mature global value chain networks.

Research Findings

A 2007 study identified an emerging global logistics model that has now become a mature model for high value, lightweight, and non-dangerous global products (Su, 2007). Due to the heat-up of competition among major notebook computer brands in the global consumer market, these brand name companies such as HP, Apple, Lenovo, and Acer have started to tighten up their control of their supply chains and raised the production and service delivery requirements to their original design manufacturers (ODMs) and third-party logistics (3PL) service providers. To cope with these stricter requirements, ODMs started to work with their brand name customers and global logistics firms on developing a Just-in-Time (JIT) supply chain that would not only meet the global distribution requirements, but also surpass the expectations of the end customers or consumers. This JIT supply chain is defined as the Global Direct Distribution Business Model (abbreviated as GDD), which combines and synchronizes the fast production cycle and the fast delivery cycle of global products similar to that of notebook computers. With GDD, it is possible for global marketers to centralize production or warehousing in the global supply chain and distribute products to many destinations in the world, as if they are distributing their products domestically without using any trade middleman. This model has now become a critical facilitator for the fast growing cross-border e-commerce businesses in Asia.

In 2015, the *International Journal of Physical Distribution & Logistics Management* published a special issue on "Contemporary Strategic Supply Chain Management and Logistics Issues in Asia" (Su, 2015). A total of 43 papers were submitted. The most prevalent topics are supply chain collaboration/integration and green supply chain strategic issues in Asia. Asian supply chain risk and 3PL are also popular topics. The following topics were also submitted: sustainability, e-commerce, service orientation, and logistics innovation. One intriguing paper examined the very unique topic of logistics corruption in Asia. For research methods, nearly half the papers submitted employed survey-based empirical research methods such as regression analysis, structural equation modeling (SEM), and factor analysis. Case-based and optimization-based methods were also both well represented. This special issue showcases the diverse strategic supply chain management (SCM) and logistics research interests in Asia, as well as the highly diverse nature of Asian economies. Two representative research findings will be presented next.

Ke et al. (2015) used annual US trade statistics and manufacturing industry data for the years 2002–9 between the United States and its top 12 Asian trading partners to examine key factors associated with the international transport modal decision. The study findings indicate that manufacturing industries use more airfreight and less ocean freight when facing positive sales surprises, high monthly demand variation, a high contribution margin ratio, a high cost of capital, and increased competition. While transportation cost remains an important concern, a logistics manager must also consider non-cost factors such as competition, working capital, and demand uncertainties in their modal decisions.

Pujawan et al. (2015) presented a new method for integrating operational and strategic decision parameters, namely, shipment planning and storage capacity decisions under uncertainty for the maritime logistics of bulk shipments of commodity items. The results suggest that the number of ships deployed, silo capacity, working hours of ports, and the dispatching rules of ships significantly affect both total costs and service levels. Interestingly, the study findings indicate that operating few ships enables firms to achieve almost the same service levels while gaining substantial cost savings if constraints on other parts of the system are alleviated, that is, storage capacities and working hours of ports are extended.

A longitudinal single case supply chain study recently published (Cui et al., 2019) explores a global heavy vehicle manufacturer's servitization process in the Chinese trucking user market with many 3PL firms as its customers. The key research finding reveals that the decision-makers adjust their decision-making logic depending on the stage of the servitization process and associated risk patterns. As the servitization process evolves into a more sophisticated stage, decision-makers will change their decision-making logic from a causation dominant logic to an effectuation dominant logic, in order to cope with the increased risks. Effectuation theory originally developed from entrepreneurship research and is found to be a valid theory for the explanation of the risk and uncertainty control behaviors in the servitization transformation process of manufacturing firms.

Asian Logistics Performance

Logistics disparity among nations or economies has caused both hard and soft connectivity issues for the intra- and inter-Asia trade routes and subsequent time delay and additional logistics costs in global supply chains. The World Bank has recognized the critical role of national logistics performance in the effectiveness of world trade and also the gaps of logistics performance among nations. Thus, since 2007, the World Bank has initiated a biannual global survey on national logistics performance for most countries in the world and has developed a comprehensive *logistics performance index* (WB LPI) database, examining six logistics performance indices: *customs, infrastructure, international shipments, service quality, tracking and tracing, and timeliness*.

National logistics is not a stand-alone system, rather it is a complex interorganizational and, oftentimes, cross-country set of processes prone to degenerate if not managed on a continuous improvement basis. Even until now, for many countries, it is still a highly challenging job to measure and manage their national logistics performance due to its cross-ministry administrative nature and many other complexities involved in moving international goods across national borders. The WB LPI database is currently the only source that provides the national logistics performance measures for most countries in the world. Previous studies have found

Table 2 Asian subregional LPI comparison

Asia subregion	LPI average			LPI standard deviation		
	Score	Relative scale	Rank	Score	Relative scale	Rank
Central Asia (5)*	2.54	1.00	108	0.18	1.00	25
East Asia (6)*	3.52	1.39	38	0.59	2.87	46
East Asia-M (5)*	3.75	1.48	19	0.20	5.66	10
North Asia (1)*	2.76	1.09	75	0.00	1.43	0
South Asia (8)*	2.53	1.00	105	0.35	1.02	36
Southeast Asia (9)*	3.06	1.21	60	0.51	1.79	39
West Asia (14)*	2.88	1.14	74	0.49	1.45	42

(n)*, n is the number of the countries in the subregion; East Asia-M, East Asia excluding Mongolia; relative scale, the relative LPI scale of a country to the worst performer.

Table 3 Top and bottom LPI performers in Asia subregion

Asia subregion	Top LPI performer		Bottom LPI performer		Gap
	Country	LPI rank	Country	LPI rank	
Central Asia (5)	Kazakhstan	71	Tajikistan	134	–63
East Asia (6)	Japan	5	Taiwan	27	–22
East Asia-M (5)	Japan	5	Mongolia	130	–125
North Asia (1)	Russia ^a	75	Russian	75	0
South Asia (8)	India	44	Afghanistan	160	–116
Southeast Asia (9)	Singapore	7	Myanmar	137	–130
West Asia (14)	UAE ^b	11	Iraq	147	–136

^aRussian Federation

^bUnited Arab Emirates

Source: Extracted and compiled from 2018 full LPI dataset from the World Bank (<https://lpi.worldbank.org/>)

that better LPI scores are associated with more trade and lower logistics costs, while a few studies have indicated that the relationships are nonlinear. One study even developed a process-based benchmarking method to facilitate the management and continuous improvement of the national logistics performance of a country or economy (Su and Ke, 2017).

Asia can be divided into seven subregions. Only Russia is a single-country region, while all other subregions are multiple-country regions ranging from 5 to 14 countries/economies in the WB LPI database. Table 2 clearly shows East Asia (without Mongolia) leads in Asia in terms of average LPI score and rank, with large relative gaps surpassing the lowest performers—Central Asia and South Asia, that is, 48% versus 5.66 times higher, respectively. Furthermore, other than North Asia with only a single-country Russia, Asian subregions internally also demonstrate logistics disparity, with different degrees of LPI score and rank standard deviations. Central Asia has both the lowest LPI averages and standard deviation, which implies that all countries in the subregion might suffer from poor logistics connectivity and stagnating economic development. Table 3 provides a view of the top and bottom LPI rank performers in each subregion and the gap between top and bottom performers to elaborate the findings from Table 2.

The extended LPI analysis results in Tables 2 and 3 reinforce the World Bank's claim that logistics disparity exists among nations/economies and has become a hurdle to global economic and trade development. The Asia Development Bank estimates that between 2016 and 2030, an investment of US \$8.4 trillion in transport infrastructure will be needed to address the shortfall of transportation connectivity in Asia. Countries have responded by upgrading aging and/or developing new transport infrastructure, as well as more ambitious initiatives like China's "One Belt, One Road" initiative. Relative to major hubs elsewhere in the world, Asia is under-provided with modern logistics space; only Shanghai, Tokyo, Hong Kong, and Singapore match the supply elsewhere—and even then, only the smaller global hubs. Asia—developing Asia, in particular—lags the industrialized world in terms of logistics facility supply and sophistication, presenting a significant opportunity for real-estate investors and developers.

Asian Logistics Industry

In the last 20 years, accompanying the rapid economic growth globally, particularly in Asia, the 3PL industry (i.e., the logistics outsourcing industry) has evolved in a revolutionary manner into a global service industry booming in both developed and also emerging economic blocks. There are several industry survey reports for the global status of 3PL development. One that has a long

Table 4 Global 3PL revenues

Region	2014 global 3PL revenues	2015 global 3PL revenues	2016 global 3PL revenues	2017 global 3PL revenues	Percent change 2015–16	Percent change 2016–17	Percent change 2017–18	CAGR 2010–17
Africa	29.6	27.1	25.5	26.1	−8.4	−5.9	2.4	1.30%

history and recognition is the Annual Third-Party Logistics Study (Langley and Infosys, 2019). The most recent release of the survey analysis report is the 23rd Annual Report in 2019. It is worth extracting some of its findings for this article, particularly relating to Asian logistics.

Third-Party Logistics Development

Table 4 shows global 3PL revenues by region from 2014 to 2017, and the year-over-year (YOY) percentage increases or decreases. Global 3PL revenues increased to \$869 billion in 2017 from \$804.2 billion in 2016. This reflects a strong global growth in the 3PL market of +8.1% from 2016 to 2017. The last column in the table indicates the CAGR of global 3PL revenues was calculated at +3.5% from 2010 to 2017. This is a clear indication that the 3PL industry has been a growing industry over the last decade. Globally, the Asia Pacific region is the largest logistics outsourcing market, accounting for 38% of total global 3PL revenues; North America with 25% share comes next; and Europe with 21% is in third place. The three regions together control more than 80% of the world 3PL market.

To keep up with the increasing level of complexity within the supply chain, companies must be agile enough to meet rapidly changing environments. Shippers are continuing to leverage what 3PLs offer, allowing them to optimize the supply chain, minimize costs, and create value, as well as to align expectations as a key to achieving success for both parties. Logistics is being transformed through the power of data-driven insights, and current technology is enabling unprecedented amounts of data to be captured from various sources along the supply chain. The use of technology is exploding within every area of the supply chain, which is driving increased agility. Shippers are increasingly aware that if they do not have the technological capabilities to accomplish their goals, they should partner with those that do. As the amount of available data increases, shippers and their logistics partners will need to be able to take the information and make it relevant, as many 3PLs are already making significant investments in technology that allows them to analyze shippers' operations.

A report released by Armstrong & Associates, Inc. (2017) shows e-commerce and outsourcing are fueling demand for 3PL services, driving 3PL revenues to over US\$1.1 trillion by 2022. Recent projections by Armstrong & Associates indicate optimism for the growth of global 3PL revenues into the next 5 years. Among the factors contributing to the likelihood of continued growth are data-driven technology, increased capacity and demand, and overall rising prices.

Research Findings

Since the early 1990s, 3PL services have evolved into a highly innovative and competitive global service industry and, as such, have attracted great research interest from supply chain and logistics researchers. Few Asia-related 3PL studies can be found, even though a number of Asian 3PL studies are growing. Two highly recognized international journals have published two special issues regarding logistics development in the Greater China area: an immense and diverse geographic area that includes Mainland China, Hong Kong, Macau, and Taiwan. Over the last 3 decades, there has been a tremendous influx of financial and human capital that has contributed to the development of a complex and dynamic mix of domestic and global supply chains. Moreover, rising labor and rent costs, stricter environmental regulations, escalating trade conflicts, and regional political instabilities have dramatically impacted and changed supply chains in the region. Rapid changes make collecting empirical data for strategic SCM research studies in Greater China somewhat challenging for multiple reasons.

In 2009, the *Transportation Journal* (Vol. 48, No. 3) published a special issue to better understand the transportation and logistics-operating environment in the Greater China region. Five papers were selected for the special issue with only one relating to 3PL development. Cui et al. (2009) conducted a pioneering 3PL innovation study and compared three mid-size regional 3PL firms from Hong Kong, Sweden, and Taiwan. How the 3PL firms innovate illustrates the characteristics of different regions. Many firms enter China for sourcing and outsourcing. They have the need for cross-border operations and require customs-related services and international transport from innovative and highly motivated regional 3PL firms. Hong Kong is the logistics center in

East Asia and companies tend to choose Hong Kong as a distribution center for their global pipelines and regional 3PLs constantly develop new services related to distribution and operation. In contrast, Sweden is in a more developed region. Firms focus more on sophisticated end consumers in this region and 3PL providers concentrate on providing new services to their clients in order to meet end consumers' needs. This pioneering 3PL innovation study laid out a foundation for a 3PL innovation competence assessment study that developed a 3PL innovation competence assessment methodology based on the 3PL and innovation literature (Su et al., 2014).

In 2017, an *International Journal of Physical Distribution & Logistics Management* special issue (Vol. 47, Issue 9) on the strategic supply chain and logistics management in Greater China provides several valuable research findings on 3PL firms (Su, 2017). In general, the special issue recognized that the 3PL industry in Greater China has experienced rapid growth in recent years and demand for logistics services has grown tremendously. Meanwhile, 3PL firms in the region are facing intense competition in the logistics market, and such competition has forced many 3PLs to reconsider their competitive advantages from a resource-and-capability point of view. Nevertheless, logistics users' satisfaction with 3PLs in mainland China is lower than the level of satisfaction found in more developed countries and the range of logistics service provisions seems to be much narrower.

The four 3PL papers published in this special issue reveal the crucial status regarding the contemporary strategic development of 3PLs in the Greater China region. Interestingly, the four papers all use structural equation modeling as the key research method for their data analysis, showing the popularity of more advanced statistical methods among Greater China logistics and SCM scholars who conduct survey-based research. Three papers examine 3PL topics from the resource-based view (RBV) of the firm and the factors affecting horizontal alliances and firm performance, while the other paper analyses the views of 3PL customers regarding the relationships between dependence and integration, with trust as the mediating factor. Two papers in the special issue are selected to present their research findings in this article.

Shou et al. (2017) build on extant research to examine the effects of relational resources on firm performance in the Chinese logistics industry, surveying randomly selected 3PL providers across different regions in China. The results of this research confirm that relational resources have a positive effect on firm performance. However, such an effect is not direct; instead, it is realized through the mediation of the innovation capability. This finding corresponds to the core idea of the RBV, which argues that firms deploy strategic resources through capabilities in order to achieve competitive advantages and superior performance.

Gao et al. (2017) explores the impact of partner similarity on the success of horizontal alliances of 3PLs in China. Primary data were collected through questionnaire to 380 Chief Executive Officers and Managing Directors in 262 small- and medium-sized logistics enterprises in China. This research verifies that partner similarity and logistics alliance management capability are positively correlated with alliance stability and performance in horizontal alliances among Chinese 3PLs, especially where competence and cultural similarities are present. Moreover, alliance stability mediates the impacts of partner similarity and logistics alliance management capability on alliance performance.

The Future

As the Asian economy moves toward a new level of uncertainty and complexity in the global environment, the logistics services and support to Asian businesses and customers will definitely continue to transform to a more agile form, in order to cope with the changing and increasingly demanding service requirements from the markets. For logistics practitioners, ample growth and business renewal opportunities certainly exist in Asia and can be captured by those who are prepared. For logistics/supply chain scholars, many challenges need to be addressed regarding developing better educational programs to train the next generation of Asian logistics managers and analysts. The opportunity also exists for researching critical emerging topics to better understand Asian logistics development that is becoming more dynamic and complex, in order that organizations can formulate better logistics policies and strategies.

Introduction

Logistics performance has emerged as one of the important ingredients for trade competitiveness for firms and countries. Logistics systems help firms and producers to reach markets at the domestic, regional and international levels. The systems also play an important role in a country's ability to participate in global value chains. Trade logistics refers to the process of planning, implementing, and controlling the efficient flow and storage of internationally traded goods, services, and related information from point of origin to point of consumption. The logistics system comprises a wide variety of activities that include transportation, distribution, packaging, warehousing, and supply chain management and consulting services, among others (Fig. 1). Logistics systems are a network where the quality of services is a function of the level and type of demand that has to be served, the availability and efficiency of core infrastructure, the sophistication of the services, and the effectiveness and appropriateness of the regulatory regime in a particular country. The services have to continuously evolve with changes in any one of these variables, but especially demand.

The flow of goods in trade logistics is structured in supply chains. A supply chain is a system of people, technology, activities, information, and resources organized into activities for moving a product or service from supplier to customer. Given the variety of elements, the efficiency of a logistics system is determined by how well the constituent components function together, and their ability to offer seamless services to shippers. A supply chain is designed for specific types of goods or services moving on a specific route. The logistics services used in the chain can be modified to meet a specific objective with regard to the time, cost, and reliability. In developing economies, the main flows are primary products, linked especially to the agriculture and mining sectors and a few manufacturing or distribution firms that together generate the core demand for logistics services, as they have to move inputs needed for production and products that are needed elsewhere or to supply the market.

Figure 1 Core elements of an International Logistics System.

Measuring the Performance Efficiency of Logistics Systems

There are a few core metrics that are used to measure the performance of a supply chain. The most common measures are time and its variance to reach target markets and the cost of shipping goods.

The time it takes shipments to reach their destinations is an important consideration in logistics. One of the predicaments in developing countries is that their dominant economic activities, typically agriculture, generate time-sensitive products and yet, at the same time, their logistics system performance is not always suited to speedy deliveries. As a result, the incidences of postharvest losses are very high, as products deteriorate on the farm, during transfer to market or at the market. The small scale of production can result in lengthy delays before products are collected, or if the consignments are collected individually, then the unit costs of logistics become very high. A possible solution that is often used in advanced economies is to have scheduled services. However, individual farmers are typically not able to sustain regular supply. Consequently, the market depends on on-demand services and spot pricing of services. There is limited use of long-term contracts, except in the case of larger firms or cargo consolidators. Spot contracting generally comes with high prices and often discourages service providers from upgrading their services and can result in frequent mismatches between demand and supply of logistics services. In contrast, long-term contracts, typical of economies with thick markets, allow for a better distribution of risk, by assigning it to the party in the best position to manage associated risks. In addition, long-term contracts also provide a formal mechanism for coordination between logistics service providers, as typified by multimodal transport contracts.

The reliability of logistics systems can often be more important to traders than the actual time. A trader needs to be sure that the goods will arrive as expected, so even if the transit time is a few days longer this can be allowed for in the production and delivery schedule, whereas uncertainties (especially in the transit time) require an allowance that is greater than the uncertainty. Where uncertainties in the time required for supply chain activities occur, they will propagate down a supply chain, often becoming more magnified as sequential schedules are missed. In order to avoid these problems, shippers either store larger volumes in warehouses and storage facilities or introduce slack time into their schedules. Logistics in developing economies is therefore characterized by large volumes of products in storage or frequent stockouts as a consequence of unreliable systems. Storage and inventory costs can therefore be very high—or alternatively, shippers are excluded from some markets due to an inability to guarantee reliable supply.

Ultimately the direct cost of logistics, usually monetary, is the performance measure that producers in developing economies pay the most attention to. Individually, the producers are price takers and therefore are not able to influence price trends in the market. They therefore pay attention to cost in order to retain market competitiveness. In many instances, freight rates are the largest component of direct costs. The rates typically reflect the balance or rather, imbalance in traffic flows that are observed in most developing economies. There is usually one dominant direction of goods flow, often associated with agricultural seasons. In many cases, prices during the peak season are set above the long-run marginal cost and the rates for backhaul cargo during slack seasons set at the marginal operating cost. Even then, when averaged over all shipments, prices tend to be set above the average cost, to cover for unreliable demand. It is also quite common in many developing countries for costs to include charges that are informal, to expedite shipment or processing of products through regulatory controls. However, the administration of the informal payments is often very opaque, which makes it difficult to ascertain the ultimate beneficiaries.

There are significant seasonal variations in logistics flows and prices in many developing economies, in concert with agricultural cycles. Often, periods of peak demand lead to rates that are significantly higher than during off-peak periods. For instance, in road transport there is usually a high level of competition but access to certain trades, such as transit cargoes may be restricted, while other markets such as port imports or commodities requiring special vehicles, may be vulnerable to cartels. Rail freight rates are often determined through regulation, but increasingly are set relative to road transport rates.

Often, there are trade-offs between the various performance measures of logistics. The most common trade-off is between time and cost. Generally higher value products give greater importance to time because of the impact on the costs of inventory in transit, as well as the higher value the consumers give to immediate availability. The opposite applies for lower value products. However, for most products there is a differentiation between the value of time for large orders and for restocking. Where demand is volatile, a third category or rapid restocking places additional emphasis on time.

Key Bottlenecks in Logistics

There are a variety of bottlenecks that affect the performance of supply chains by increasing costs, delays, and the unpredictability of arrival. These may be physical constraints associated with a lack of capacity or diminished throughput. The effect of the bottlenecks is magnified in sequential activities, as uncertainties become more pronounced. They may result from delays in the processing of documents and payments or other procedures that temporarily interrupt the flow of cargo.

Global indices such as the World Bank's Logistics Performance Index (LPI) show that the logistics performance of low-income economies as a group lags behind that of middle- and high-income countries (Fig. 2). For instance, the 2018 edition of the LPI shows an average score of 2.35 out of 5 for low-income economies compared to 2.57 and 3.14 for middle- and high-income economies, respectively. On average, low-income economies have scores that are 48% below the average performance of high-income countries. Weaknesses in the logistics performance of low-income countries in particular are across all the dimensions of the LPI, covering infrastructure, logistics competence, quality of services, customs, ability to track and trace shipments, and ability to manage

Figure 2 LPI performance by Income Group, 2018. *Source:* Own estimates based on World Bank, 2018a. Connecting to Compete: Connecting to Compete 2018, Trade Logistics in the Global Economy, The Logistics Performance Index and Its Indicators. World Bank, Washington, DC.

international shipments. The causal factors behind these recorded system attributes are many, reposed in infrastructure, regulatory regimes and institutional mechanisms.

Various factors affect the efficiency of transport services. In addition to the condition and congestion on the right-of-way, which determine the average velocity, there are delays at the various intermodal and intramodal nodes. These delays arise due to difficulties with problems of productivity and congestion at the nodes as well as synchronization of the connecting services. These become more problematic during periods of peak demand, when there is a loss of capacity or where quotas are introduced on the services that receive the shipments.

A major source of high costs of logistics in developing countries is the thin and fragmented demand for logistics services. Freight rates are affected both by the industry-wide factors and the characteristics of individual shipments. Two critical factors are the size of a shipment and the potential for finding a backhaul cargo. The latter, which can reduce freight rates by as much as 40%, is especially problematic from cross-border movements where the return cargo is limited to cargoes destined for the same country from which the cargo originated. Significant savings can also be obtained by shipping full container loads, truck loads, rail wagon loads, and airfreight shipments of 500 kg or more. For rail transport there are significant savings for longer trips due to the time spent loading and unloading trains. The same applies for road transport because of the cost for mobilization and return to the dispatch point. For shorter distances, the cost is dependent on the number of trips that can be made in a day.

There are significant economies of scale in logistics services. Wide bodied aircraft, Post-Panamax container vessels, larger trucks, and rail wagons, all offer significant savings because of lower fixed costs per ton of capacity and lower fuel consumption per ton-kilometer of capacity size and capacity of transport units. Investments in the extension of runways and deepening of port entrances are meant to reduce the cost of transport by attracting larger, more efficient aircraft and vessels. The conversion to broad gauge and strengthening of rails that is taking place in South Asia and East Africa is partly meant to accomplish the same for rail transport. A reduction in road transport can be accomplished through strengthening pavement and increasing the weight capacity of bridges. However, a challenge in developing economies is that the average shipper generates only a relatively small amount of cargo and it is usually only possible to reduce costs in the short run by increasing the average load factors and annual utilization for existing transport units.

On services, one major variable is the level of competition for services and differences between peak and off-peak demand. The degree of competition within the logistics sector, for both transport and nontransport services, is important for both the efficiency and variety of the services provided. For the transport sector, there are obvious issues of public sector restrictions through quotas, standards, and financial requirements, but also indirect constraints related to taxes on equipment, access to finance and lack of security and safety on the road network. For nontransport logistics, there are various opportunities for public sector restrictions through licensing and certification, but these are rarely a problem. More common are limitations on the participation of foreign service providers. The principal constraint for local service providers is the preference of foreign importers and exporters for using international logistics service providers, though this does not prevent local service providers from entering into various forms of partnership with their international counterparts.

Competition within and between modes is another important factor in reducing the cost of transport and can also play a role in increasing the quality of service. The extent of competition can be determined for each mode, but applying different measures in each case. For road transport, the size of large trucking firms and the number of such firms provides such a measure. In most cases, the large companies will hire independents, but this form of subcontracting does not affect the level of competition. While rail transport is usually provided by a single company, the competition from road transport is usually intense. Information on the market share for freight transport usually indicates a small market share and most of this is dominated by shipments of petroleum and minerals. The exception is for container movements where there are large inland container depots located far from the port. While international air freight and ocean shipping are relatively competitive, the former is often limited by bilateral agreements and restrictions on the carriage of cargo. A more significant constraint on competition is the cargo handling operations at the airports and seaports. Increasingly, these services are being provided by private operators having concessions obtained through competitive bidding. However, national airlines continue to have a strong presence in cargo handling operations and the port authorities often participate in the regulation of cargo handling charges while collecting royalties from the concessionaires. The results have only a modest impact on the efficiency of operations but can result in excessive charges for these services.

Market failures can also occur because of lack of knowledge on the part of the participants or because of external events. The most common of these is excess supply and capacity, especially in transport services, which leads to a sharp decline in rates and degradation in the quality of service. However, there is also the failure of shippers to plan strategically and treat logistics as part of their value chain rather than as a cost. Although there is widespread recognition of the need to diversify exports and move up the value chain, there is frequently a failure to appreciate the importance of logistics in achieving these goals. The same applies for imports, albeit in a less competitive environment.

In terms of international logistics, the main weaknesses in developing countries are typically the trade facilitation environment and, especially, the performance of main trade gateways, particularly seaports, airports, and border crossings. These dimensions are part of the trade facilitation agenda which refers to the ease of clearance of goods, including the movement of cargo through international gateways. Efforts to improve the efficiency and transparency of trade facilitation core functions have to be an ongoing endeavor. The basic problems in developing countries are delays, informal payments to expedite clearance, lack of transparency, and limited compliance with regulatory requirements. Uncertainty in the time required to clear cargo, especially imports, limits the ability to introduce more efficient distribution systems and reduce inventory in the supply chain. Because of the importance of exports to a country's economies, most countries have largely eliminated the delays for clearing export cargo, thereby reducing delivery times and allowing for scheduled movements from the factory to the final destination.

Even in the case of imports, there have been significant improvements over the last decade. For a significant proportion of companies, imports with proper documentation can be cleared within a couple of days versus 1 day or less for exports. In a growing number of countries, the percentage of import shipments subject to physical inspection has decreased to 20% or less, while the number of shipments covered by various programs for expedited clearance is increasing from lows of 20% to highs of 80%–90%. These figures apply to the total trade, most of which moves through seaports. The clearance time at land borders and airports is much less, but so are the requirements. The delays in clearing cargo at ports only affect the cargo whereas at the land borders they also affect the movement of vehicles and therefore the cost of transport. Therefore, delays for more than 4–8 h increasingly are unacceptable. Airfreight is more demanding because the impact of delays at the airport have a greater impact on total delivery time. Airfreight is used where the value of time is extremely high. Any delay in clearing import cargo beyond 4 h is considered excessive.

The productivity of the gateways, as measured in terms of the cargo dwell time, is of paramount importance. Many of the factors affecting gateways apply in general to intermodal and intramodal transfer points. The efficiency of these transfer points is improving as a result of greater coordination between the transport operators delivering and receiving the cargo. Increasingly, these are the same company which either control the transport services on both sides or control one and subcontract the other. In some cases, these movements are controlled by a third party which contracts both services. The capacity and efficiency of these hubs are also being improved as the technology used in the gateways is transferred. Inland container depots, logistics hubs, and urban truck terminals have all been upgraded to provide faster transfer of cargo and better tracking of cargo movements.

Improving Logistics Performance in Developing Countries

Understand the Demand and Benchmark Logistics Performance

What an economy trades matters a lot in logistics. The logistics system has to be able to meet the needs of the specific products that are already traded or those that a country aspires to trade. A first step in improving logistics performance is to understand the nature of the demand. There are a variety of national and international sources of trade, transport and logistics data that can be tapped. The data should allow a review of the country's trade to identify those that are important, growing, or otherwise of strategic importance. They should also provide information on both volume and value for the trade in specific commodities. Information on traffic volumes is available from international sources, but greater detail is available from annual statistical reports prepared at the national level or by specific organizations. The latter are increasingly available on the web.

Based on the data collected, benchmarking can be implemented to assess how well supply chains or an economy is performing compared to others with which it competes. Various indices assessing the quality of logistics services have been developed in recent

years. However, most indices measure overall performance which is determined by a combination of private service providers and public regulators. They all provide an aggregate measure. Ideally, the data should be at a disaggregate level to offer granular insights about the performance of specific supply chain components.

Define Comprehensive Logistics Strategies

Logistics in many countries is characterized by fragmented service provision, regulations, institutions, and modal imbalances. Many countries have more than one mode of transport but most traffic is carried by road. This results in severe congestion on the roads, underutilized railways and other systems that may exist, and increased negative impacts on climate. In fact, each system would have evolved as a discrete layer in the overall network with limited integration and coordination of investments and operations across the different networks. The separation of the networks is reinforced by the institutional arrangements for the transport sector and the regulation of logistics services which are similarly fragmented. Emphasis should be placed on enhancing planning and strategic development that are optimized to minimize system costs, from a development and user perspective. Emphasis should be on multimodal systems of logistics. Consideration should be given to rationalizing or at least coordinating the agencies that are involved in providing logistics infrastructure and services. In addition, any strategy should be codeveloped together with the private sector, shippers, and services providers, as major stakeholders (Oxera, 2017).

Develop and Maintain Infrastructure

There are many studies that point to large infrastructure backlogs across much of the developing world. The symptoms of poor infrastructure are congestion, poor service quality, and poor connectivity. Filling the infrastructure gaps is important, but how to finance it has become one of the major issues. Increasingly, governments are turning to the private sector for infrastructure financing. There is great potential for the private sector to finance network improvements, as well as having responsibility for the management of transport and logistics systems. Most success has been registered in parts of the systems with guaranteed revenue streams, such as ports and airports, but also railways and more and more highways, especially in countries with high economic densities. However, care should be taken to connect lagging regions, as often they are also the poorest ones. There is also a need to move toward the standardization of infrastructure design to interconnect with neighboring countries. Ultimately, regional integration offers great potential to enhance the economic outcomes of investments in logistics infrastructure and associated services.

Improve the Regulatory Environment

A modern logistics framework should be clear on what needs to be regulated and what need not to be regulated. Obtaining the input of all relevant stakeholders is critical for a sound and well-understood legal and regulatory framework that will help modernize and develop transport and logistics services. It is also good practice when formulating legislation to carry out some regulatory impact assessment to balance costs and benefits of such new legal instruments. Overall regulation should be kept minimal and limited to only a few issues relating to safety or market failures; regulations should be accessible; and bilateral, regional, and international agreements should be taken into account. More importantly, it is critical to enforce any regulations in a consistent and nondiscriminatory manner.

A conducive regulatory regime should nurture the evolution of logistics services in concert with changes in demand (Fig. 3). Over time, a professional class of service providers, some with no physical assets, will emerge to offer sophisticated bundles of services. Since the 1980s, firms in developed economies have developed customer-oriented production and supply chain management that has contributed to increasing market segmentation. This has caused vertical disintegration as a result of companies focusing on their core business and utilizing distributed processing. Starting in the 1990s, logistics structures were reorganized to improve performance. This included reducing inventories, outsourcing transport, and establishing horizontal collaborative networks to share the costs of logistics facilities. This has resulted in an emphasis on improved scheduling of product flow—lead time management, lean and agile logistics, process mapping, and efficient consumer response. Many low-income economies are still to go through this evolution, which is very much part of modern dynamic supply chains.

Trade Facilitation

In many countries, the focus of trade facilitation is on the simplification and harmonization of procedures and documentation, with special attention given to the release and clearance of goods, including goods in transit. While most of the attention has been given to customs procedures, there is growing interest in the other regulatory procedures performed at the border. A number of standard reforms have been introduced in most countries, corresponding to the various conventions and standard practices introduced by the WTO and WCO, more recently through the WTO Trade Facilitation Agreement (Kunaka et al., 2013). The various international instruments have promoted the classification and valuation of goods, the format, submission and processing of customs declarations, the procedures for selecting shipments to be inspected and the treatment of courier services. Most of the improvements have been achieved with the use of improved IT systems.

Efforts to reduce the level of inspection have focused on the introduction of IT-based risk management systems. Traditionally, risk management is implemented through subjective judgments of customs officials. IT systems have introduced selectivity modules that

Figure 3 Hierarchy of Logistics Services. Source: Own construction after Rodrigue, J.P., 2017. *Developing the Logistics Sector: The Role of Public Policy. Technical Report*.

apply objective criteria related to the type of commodity and the source in terms of origin country and shipper. These criteria are developed through the preparation of risk profiles developed by designated customs officials. Efforts to apply statistical analysis and business analytics have begun but face significant institutional challenges as customs authorities replace their cadre of officers with personnel having modern technical skills.

Skills Development

The low skills level of logistics service providers increases logistics costs and the costs of externalities. For instance, in many countries, even in advanced economies, logistics services are labor-intensive; dominated by truck drivers, warehouse operators, and administrative personnel. The difference in low-income countries is that many of these workers are low skilled and illiterate. Besides lowering service quality, poor driving skills also contribute to road crashes. It is therefore important to invest in skills development across the public and private sector, so the various role players can continue to improve performance. Fortunately, there are increasingly many schools and universities that offer courses on logistics (McKinnon et al., 2017).

Exploit Disruptive Technologies

Disruptive technologies offer the promise of improved and even different forms of connectivity, when compared to what exists now. As such, the long-term planning of infrastructure and services needs to take into account the changes that modern technologies are feeding. The World Bank (2018b) defines disruptive technologies as technologies that result in a step change in the cost of, or access to, products or services, or that dramatically change how we gather information, make products, or interact. In logistics, they are impacting how and where products are manufactured and delivered, the speed of delivery and the management of inventory. All countries, regardless of level of income, have to take into account some the emerging patterns. This is despite that fact that past performance is no longer a good predictor of future patterns.

Introduction

In this chapter we review the different approaches and methodologies for network modeling and their main applications for freight transport. Network modeling in transportation science is one of the main areas of application of network theory. It is based on graph-theoretic principles—mathematically speaking, networks are graphs that represent relations (edges) between discrete objects (nodes), where the edges and/or nodes have properties (e.g., travel time, capacity). These conventions are the cornerstones of models of the real world of transportation networks, services and flows. In freight transportation, networks are visible in physical transport infrastructure, transport services, and even trading activities. Network models do not necessarily only represent tangible aspects of the transport system, but may also represent the availability of a service offering as potential movement, or a trading relationship as abstract connection.

The basic techniques for freight network modeling evolved from operations research (Ahuja et al., 1995). Our description of models largely follows this tradition. Applied freight network modeling for civil engineering purposes developed in the 1960s, during the times of rapid expansion of national infrastructure networks, and was extended with microeconomic models to study the regulation of network industries, like the US rail freight industry. During the early 1980s, the emphasis in passenger network modeling in transportation shifted to congested networks and traffic management (Sheffi, 1985), while in freight transport, descriptive models of broader logistics and trading processes gained momentum (Harker and Friesz, 1985).

Network models require a representation of the demand and the supply side of the market of transport services. Network design models are often applied to calculate the optimal structure of the network, or its services. In such a setting, demand and supply models can be framed normatively as interdependent optimization models. The optimal design of a network structure or its services has to follow the expected usage of the network. At the same time, the usage of the network will depend on the available network and, based on the principle of shortest or cheapest paths, optimizing the flow over the network given the available services. Users can either work together to minimize the total transport costs in the network (system optimization) or choose paths separately (user optimum). Seen from a game theoretic perspective, the framing is one of a bilevel optimization problem. Here the design of the network or services is the main problem, and determination of network flows is the underlying problem; these two have to be solved together. Economic theory adds the idea that user behavior can only be described to a limited degree using optimization; therefore, descriptive models can be used that build on ideas of optimization but also explain how users deviate from a supposedly optimal situation. These descriptive models can still be applied in a bilevel framework, but will result in relatively sophisticated network flow calculation that allows for typical behavioral phenomena like imperfect information and bounded rationality. Network flow models can also be applied in isolation, to predict the expected use of a given network, in order to evaluate impacts of transport policies or traffic management measures.

The remainder of this chapter is built up as follows. Below we first discuss the way that flows are portrayed on the network (Section “The Network Flow Model”). Section “Infrastructure Networks and Their Operation” discusses approaches to modeling infrastructure networks and their operations. In Section “Service Network Design”, we introduce the models for service network design. Section “Vehicle Routing” follows up with the related vehicle routing problems. Final section suggests some directions for new research in freight network modeling.

The Network Flow Model

In a network flow model, a network with nodes (N) and arcs (A) is given, and we try to determine the flows over this network, given a table of origin-destination flows between nodes. We will generally assume that flows will try to follow paths through this network such that supply and demand in each node is satisfied and transport costs through the network are minimized. To this end, we also

assume unit costs through the network for each arc (noted by c_{ij}). The general mathematical formulation of the minimum cost flow problem is as follows:

$$\text{Minimize } \sum_{(i,j) \in A} c_{ij}x_{ij} \quad (1a)$$

$$\text{subject to :} \\ \sum_{\{j:(j,i) \in A\}} x_{ij} - \sum_{\{j:(i,j) \in A\}} x_{ij} = b(i) \quad \forall i \in N, \quad (1b)$$

$$l_{ij} \leq x_{ij} \leq u_{ij} \quad \forall (i,j) \in A. \quad (1c)$$

The objective is to find an arrangement of flows x on arcs (i,j) such that the network total of the products of arc flow volumes and unit costs are minimized. The first constraint relates to the node flow balance—outflow minus inflow has to equal the supply (positive balance) or demand (negative balance) of each node. The second relates to the bounds of the arc capacities (mostly zero as lower bound and a highest flow value due to service or physical limitations to flow).

Starting from this general form of the minimum cost flow problem, many extensions are possible. Extensions can be formulated by a broader interpretation of the term network than relating only to the single mode, single user, single good, fixed unit cost case.

- The assumption about the dependence of the link unit costs c upon the flow x , or $C(x)$, is crucial for applications (indicating congestion or economies of scale). Convex cost functions, where C increases with x , allow the calculation of a global optimum, or equilibrium solution, for a network. Nonconvex functions, where C decreases with increasing x , do not exhibit one global optimum. There will be multiple solutions of such networks, only distinguishable through the starting conditions.
- Single commodity flow problems relate to one origin and one destination. Multicommodity problems include several origins and destination and will have a unique, flow-dependent constraint (1b) for each origin destination pair. Second, commodity attributes may differ across the network. If flows from multiple O/D pairs use the same network, they will compete for scarce capacity on that network. In some multicommodity applications, the optimization will not involve the minimization of the costs of all flows together, but of groups of flows individually, each trying to minimize their own costs. This is typically the case in a multicarrier network where cooperation does not exist, but flows use one and the same network.
- Multimodal networks include links representing different modes of transport, including transshipment between these modes. Beyond the individual links, services that connect links or even modes of transport can also be defined. Links may represent transshipment movements, and paths will then indicate intermodal transport chains, where goods are passed from one mode to another.
- Network models may also include choices that relate to nonphysical aspects such as departure time, or volumes of demand and supply. The first problem will involve multiple networks for different periods of time, where the user can choose which network to enter. The minimum cost solution can be calculated in the extended network as before, but now the solution will implicitly include the choice of the time of travel. In the second problem, demand and supply is assumed variable and dependent on network costs—responding positively to cost reductions and negatively to cost increases. This also creates an additional layer in network models, which can be mathematically included in the network optimization formulation. Solving the extended optimization problem will also result in an equilibrium state of the demand and supply of each node. These applications are known as extended freight network equilibrium models or spatial price equilibrium models.

Applications of network flow models are essentially predictive in nature, that is, meant to describe the expected use of the network under different future network and policy scenarios. Because of that it is essential to validate these models against observed behavior of network users. Users will often not follow a simple cost minimization logic, in many respects. In the simple form as formulated above, the network cost is an abstract term and may be related to any cost measure such as distance, service rates or time. In practice, many dimensions of costs will matter and will lead to a multidimensional formulation of link costs, including all important components. Standard practice is to use a weighted linear, so-called generalized cost function. In addition, recognizing variations between users and various uncertainties that determine individual behavior, probabilistic approaches become important. These phenomena have led to the development of sophisticated network choice models that depart from the assumption that a flow can only choose one link between two nodes. If there are alternatives, choice will be probabilistic. At the individual level, this leads to choice probabilities. At the aggregate level, this leads to a spread of flows of multiple users over multiple alternatives. Discrete choice, random utility models constitute the state of practice here today. Effectively, they add another constraint to the basic formulation, forcing flows between origin and destination nodes to follow a path dictated by probabilities of choice that conform to observed choice behavior of users.

Infrastructure Networks and Their Operation

Network design focuses on the strategic design of infrastructure. It is a joint decision about the design of infrastructure and its operation. The infrastructure design deals with the decision on establishing facilities as well as their connection topology. The infrastructure operations decisions focus on the assignment of the customers to the facilities and the routing of customers' demand

Figure 1 Network topologies.

in the designed network (Contreras and Fernandez, 2012). The problem looks to optimize an economic (e.g., total transportation cost), an environmental (e.g., congestion, CO2 emissions) or a social (e.g., service accessibility) function.

The network design problems are generally presented on a multigraph $G(V, A)$. The set of vertices represents a potential facility location and/or customers. Two types of arc exist in this graph. The first type is used to present the transportation of commodities in the network. Commodities could represent a specific origin-destination pair or specific material type. The second types of arcs/edges are used to model the network topology and the allocation of customers to the facilities (Fig. 1). In location planning, facilities may need to be connected with certain rules. For example, for the case of the railway network, facilities may need to be connected as a ring or line. Another example will be the design of the distribution network for postal service in which facilities (local and regional hubs) may need to be connected hierarchically (Laporte et al., 2015).

In the general network design problem, facilities have different functions and roles. They can either act as the sender/receiver of the commodities or as a transshipment point for consolidation. In the literature, the well-known facility location problem can be seen as a specific case of the general network design problem, in which facilities operate as a sender or a receiver of commodities. In the classical facility location problems, it is assumed that facilities are disconnected. The design decision is then limited to the selection of facilities. Similarly, the operational decision is limited to the allocation of customers to the facilities. In the p -median problem, the decisions are to select p facilities and allocating each customer to the selected facilities to minimize total transportation cost. By relaxing the number of selected facilities, the fixed-charge problem looks to simultaneously select facilities and allocate customers to minimize the total weighted cost (cost of establishing facilities and serving customer demand). The p -center problem is another variant of the p -median problem which aims to minimize the maximum cost. In recent years, studies have shifted toward the general problem in which the network topology plays a key role in the service. These problems have application in the multiechelon production-transportation system.

In some logistics systems, facilities act as a transshipment point, where flows between users are consolidated at the facilities and then rerouted to the final destination. This problem is the subject of studies in the network design problem. Early studies develop models based on topology in which all facilities are connected. The design decision is then limited to the selection of facilities and operational decisions that focus on the allocation of customers to the facilities, and routing of commodities in the network. Also, it is assumed that facilities have an unlimited capacity to process customer demand. This assumption facilitates the formulation approach, as one can prove that at most two facilities have to be visited between every pair of customers' demand. Similar to facility location problems, the p -median problem aims to locate p facilities to minimize the total transportation cost. The p -center problem aims to select p facilities to minimize the maximum transportation cost. In recent years, research studies have been performed toward the problems in which the connection of facilities have to follow certain network topology (e.g., ring, line, hierarchy).

Most network design problems are NP-Hard. For moderate size problems, they can be solved by using exact methods such as enumeration, branch and bound. For larger problems, various heuristic and meta-heuristics methods are developed to solve the problem. Interested readers are referred to Laporte et al. (2015), Mladenović et al. (2007), and Alumur and Kara (2008) for a review of the resolution approach.

Service Network Design

The service network design refers to planning freight movement over the relatively long distance between terminals with a given, or combinations of, transportation mode (e.g., truck, rail, ship, plane). For a given network, service network design looks to answer three main questions: (1) selection and scheduling of services, (2) traffic distribution, and (3) relocation of empty services. Service network design problems are modeled as the generalization of the multicommodity flow problem. Most of the exact approaches were developed based on the Dantzig Wolfe decomposition approach. Interested readers are referred to Wieberneit (2008) and Andersen et al. (2009) for an overview of the resolution approach for service network design problems.

Freight traffic assignment is a basic problem underlying service network design. This problem is an equivalent of the minimum cost network flow problem. The goal is to find the minimum cost of routing products over an existing network. Special cases of the assignment problem are the well-known shortest path problem and transportation problem. The traffic assignment problem has been extended in the fixed-charge network design problem. In this problem, products can be transported between nodes if the associated service is established. The problem can be formulated as a multigraph in which nodes represent terminals and arcs either denote product movement between nodes or a service that has been established between two nodes. Important issues to consider include (1) usually the transported demand is assumed to be constant over time. Almost all practical problems have some demand

variation. If they are not considered in the planning problem, it causes inefficiency in the capacity usage of transporters. (2) The routing of services is not always considered. In these cases, the cost associated with transport resources can be over- or underestimated. For example, in air transportation, aircraft routing is the main contributor to transportation costs. Thus, its detailed itinerary has a great impact on total transportation cost. To consistently solve the above-mentioned issues, new definitions of the service network design problem were introduced. Here, service network design is generally defined as a time-space network. The planning horizon is described as a repetitive pattern (e.g., week, month). The problem is then defined as a fixed-charge network design problem over the time-space graph. This representation enables the planners to address the rotation of services and demand fluctuation explicitly.

Vehicle Routing

Last-mile delivery problems deal with the transportation of products in which origin-destinations are in a relatively small-sized geographical area (e.g., city, country). The pickup and delivery problem is the general problem dealing with last-mile deliveries. When the transportation plan has a single origin or destination, then the problem is the well-known vehicle routing problem (Toth and Vigo, 2002). The vehicle routing problem deals with finding a minimum cost route to satisfy the demand. This problem has been extensively studied in the literature. The problem can be formulated as a network flow problem. With this approach, branch and cut algorithms are a common exact method of solution. Most of these approaches focused on introducing valid inequalities to improve computational performance. The vehicle routing problem can also be formulated as a set-partitioning model and be solved by using branch and price algorithms. Interested readers are referred to Baldacci et al. (2012) for an overview of the exact approach to solve vehicle routing problems. For very large problems, a solution to vehicle routing problems can be found by using a heuristics approach (Laporte et al., 2000).

Real-life routing problems may require to satisfy various restrictions (e.g., pickup and delivery regulations, maximum ride time, time windows). These restrictions are generalized as a rich vehicle routing problem. The term “rich” refers to various features associated with the vehicle tour (Lahyani et al., 2015). In recent years, the last-mile delivery problem is studied as integrated operational planning. The inventory-routing problem (Coelho et al., 2014) deals with inventory decisions and routing of products. Similarly, the production routing problem looks to optimize production, inventory and distribution jointly (Adulyasak et al., 2015). The difficulty of solving inventory and production routing problems are inherited from the travel-salesman problem. In general, these problems are NP-Hard and an exact method fails to solve real-life problems with a reasonable time. Readers are referred to Coelho et al. (2014) and Adulyasak et al. (2015) for an overview of the models and resolution approaches to solve these problems.

New Frontiers in Research

Advancement of information technology, innovations in transport technology and green logistics are three main trends that will shape the future of freight transport systems.

- Freight transport is one of the main contributors to air pollution. In recent years, innovations in transport technology has revolutionized transportation systems. With the introduction of electric vehicles and drones, freight transport systems have the possibility of offering emission-free services. On the other hand, they have limited autonomy. Electrical vehicles need to be recharged and drones cannot be used to carry large items. These limitations are needed to be addressed at strategic, tactical, and operational planning levels. For example, last-mile delivery can be executed by trucks and drones. With this approach, one can possibility reduce the cost while improving the response time. At the same time, the solution is required to overcome the challenge of synchronizing the operation of trucks with drones (Agatz et al., 2018).
- The growth of online retail has shifted the traditional logistics planning from offering a common low-cost solution toward personalized and swift services. In this environment, the companies need to have an insight into the customers' behavior and balance the need of customers with the operational restrictions. This is not limited to the end-user but also service providers. For example, in crowdsourced delivery systems, companies can outsource their logistics tasks (Arslan et al., 2019). However, they need to predict the reaction of each individual while a task is assigned to them. Similarly, in time-slot management systems, companies offer delivery time to the end-customers (Agatz et al., 2011). In this case, they need to know how they can distribute customers between delivery timeslots to reduce their transportation costs while making the customers satisfied.
- Sustainability has entered into network modeling as a new goal, and adds environmental and social objectives to the classical criterion of maximum efficiency. These objectives individually will generally lead to different network designs. Measures needed to reduce environmental impacts of transportation (such as collaborative routing, higher inventory levels, internalization of external costs) may negatively affect the performance of services for individual shipments. New technologies like electric vehicles, the tracking of shipments' individual trajectories and advanced emissions measurements further add to the complexity of designing sustainable networks. New approaches are needed, therefore, to reconcile the different objectives and to consider more advanced network designs (Psaraftis, 2015).

Introduction

National passenger transport models have been in use at least since the 1980s, and national freight transport models followed shortly after. Nevertheless, much more effort has been spent on passenger transport modeling than on freight, also within the subcategory of models at the national scale. National freight transport models deserve more attention because, with increasing globalization, freight transport has been growing fast, and a large part of the benefits and internal and external costs of transport (and of investments in transport infrastructure) are related to freight transport.

Important differences between the freight and passenger transport markets are the diversity of decision-makers in freight (shippers, carriers, intermediaries, drivers, operators, etc.), the diversity of the items being transported (from parcel deliveries with many stops to single bulk shipments of hundreds of thousands of tons), and the limited availability of data (especially disaggregate data, partly due to confidentiality reasons).

In this paper, we review models that are used for national transport authorities to forecast commodity flows or freight vehicle flows and the impacts of transport policy and infrastructure projects on these flows.

National freight transport models are used for different purposes:

- to assess the impacts of different types of autonomous developments (e.g., in GDP, population, and oil prices); and
- to (ex ante) evaluate the impact of policy measures, such as changes in national regulations and taxes, or infrastructure investments in specific links, nodes, and corridors.

A wide range of freight transport models and model systems [see [Tavasszy and de Jong \(2014\)](#) for a reference book] are applied by public agencies, either developed by these agencies themselves or contracted by these. Furthermore, a considerable amount of freight transport modeling takes place at universities and at the individual firm level. Models to optimize transport and logistics within a specific firm or supply chain are not discussed in this paper. However, lessons that modeling for public agencies can learn from modeling in the private sector will be discussed where relevant.

Since we restrict ourselves to national freight transport models, the focus will be on transport between regions (more or less intercity flows), not on intraregional flows. The latter are handled in urban freight models. Of course, what is being studied in a national model depends on the size of a country and its freight transport, which can vary enormously between countries. For the largest countries, a national model would mainly have to cover domestic flows, but, for other countries, a national freight transport model by definition will be an international model, containing domestic, export, import, and possibly also transit flows. Also, in interregional transport in, to, from, and through a nation, often several modes are important (road, rail, sometimes also inland waterways, and/or sea transport; possibly also air transport). Many urban models can ignore other modal competition and devote themselves to road transport only.

The Four-Step Model and Beyond

The four-step modeling structure from passenger transport has been adopted in freight transport modeling ([de Jong et al., 2004](#)) with some success ([Fig. 1](#)):

- Generation models for the production of freight transport in each of the zones and the attraction to each zone, per sector (e.g., mining) or commodity group (e.g., petroleum). The output dimension is tons of goods (transport flows) or monetary units (trade flows).
- Distribution models for the flows between pairs of zones, sometimes with a dependence of the distribution on the transport resistance between the zones from the modal split model; the dimension is tons.

Figure 1 The conventional four-step model in freight transport.

- Modal split models, in which the allocation of the commodity flows to transport modes (e.g., road, train, combined transport, inland waterways, etc.) is carried out.
- Network assignment. After conversion of the flows in tons to flows in vehicle-units, they can be assigned to networks (in some model systems the truck flows are assigned to the road networks together with the passenger cars).

Nevertheless, a comprehensive freight transport model system often requires additional steps. Some of these can be regarded as transformation modules, as in freight transport modeling the units (of measurement) may change from step to step. Freight transport model systems often start in money units, then do distribution and modal choice in tons and finally a network assignment in vehicles.

If the models for the production and attraction step use trade flows in money units, a transformation converting flows in money units into physical flows (tons) is required, since the central part of the freight model will be in tons. The conversion can be carried out using value/weight ratios by commodity group. These ratios could have a large impact on the final model predictions (in terms of tons per mode or number of vehicles per link). For this reason, it is very important to assemble good data on this conversion. Possibly, value/weight ratios can be made an endogenous, policy sensitive choice within the model system.

A second transformation that is used in many freight transport models is that for going from flows in tons to flows in vehicle units (e.g., number of heavy goods vehicles [HGVs]). This transformation is required when mode choice is in tons and the network assignment in vehicles (sometimes assignment is done directly for tons). The factors used for this are called “load factors,” usually consisting of a fixed value in tons for each mode or vehicle type. However, in reality the vehicle load is influenced by a number of decisions that are usually not modeled in freight transport models (notably decisions on shipment frequency, shipment size, return loads, and vehicle utilization rates). Alternatively, these decisions could be modeled explicitly in additional logistics modules. Also, other logistics aspects that are related to the trade-off between transport and inventory costs are usually not included in freight transport models, even though the logistics solutions of firms influence the mode split. Some models also need to produce the number of trucks for specific periods of the day, such as the morning peak and the afternoon/evening peak. Once again, this is usually done using fixed factors, not through explicit departure time choice modeling.

This brings us to the following list of missing components in the conventional four-step setup:

- Several logistics choices that individual firms are making: shipment size, use of consolidation and distribution centers; integration with production logistics;
- Scheduling: the choice of departure time (e.g., choice between peak and off-peak, day and night), as it is nowadays sometimes also added in national passenger transport models;
- Location choice for the firms and also for consolidation centers, distribution centers, and warehouses, as can be included in integrated land use-transport interaction models;
- Formation of multiproducer collection tours and multiconsumer distribution tours; however, this is much more relevant for urban freight models than for national freight models; and
- Treatment of interaction (e.g., between senders, carriers, and receivers; or even with the consumers in the household/passenger transport).

In some of these directions, considerable progress has been made in recent years; in particular, the integration of more logistics choices in freight transport modeling has been a thriving area (de Jong et al., 2012; Tavasszy et al., 2012).

A better representation of the freight transport model system in this context might be the following.

This structure has fewer steps: only three models—economic activity choices, logistics choices (including the choice of transport chain with a mode for each chain), and route choice—but each of the first two steps includes several related choices.

This model representation is consistent with the distinction between Producer-Consumer (PC) flows and Origin-Destination (OD) flows:

- PC flows are flows of goods from the location of production (P) all the way to the location of consumption. Between P and C, there could be a sequence of modes (transport chain) and vehicle types within modes, with transshipments, consolidation, distribution, and keeping inventories.
- OD flows are usually defined as flows of goods using the same mode. So every change of mode within a PC flow leads to a new OD flow.

This implies that the number of OD flows that corresponds to a single PC flow can be one or more. For instance, the PC flow with the transport chain “road-sea-road” has three OD flows. Trade data (e.g., statistics on export and import) usually are at the PC level, and transport statistics are usually collected for each mode separately and are, therefore, at the OD level. For most commodity flows, the natural decision level will be the PC flows, so that there is an optimization over the whole transport chain and not at the level of its components. However, there are also goods that are transported from the production location to an inventory and/or a port without knowing who the client at the consumption end will be. For such flows the optimization of the transport to and from the warehouse/port can be done separately, for example, by regarding them as separate PC flows (each of which could use a multimodal transport chain).

The ADA (aggregate-disaggregate-aggregate) model (de Jong and Ben-Akiva, 2007; Ben-Akiva and de Jong, 2013) follows the structure depicted in Fig. 2, and as such constitutes an alternative to the conventional four-step model, that allows for including more logistics choices. The basic representation of the ADA model is given in Fig. 3.

The ADA model consists of three submodels, two of which are at the aggregate (zonal) level, but one submodel (where disaggregation matters most) represents decisions at the level of flows between individual firms (disaggregate):

- The first aggregate submodel predicts PC matrices (this model is similar in structure to the generation and distribution models of the four-step model).

Figure 2 A revised representation of the structure of the freight model system.

Figure 3 The ADA model.

- Then comes the disaggregate submodel 2, the logistics model:
 - This reads in the base matrices of commodity flows from producers to consumers: PC flows;
 - This represents the logistics decisions (especially transport chain and shipment size choice) at the level of annual firm-to-firm flows; and
 - This delivers OD matrices to the network model (assignment);
- The second aggregate submodel carries out assignment to networks (this model is similar to the assignment models in the four-step model).

The outputs of the first submodel, the PC flows, are at the level of annual flows between two zones, within a certain commodity group. In order to serve as input in the logistics model, these flows are allocated to firm-to-firm flows in step A (Fig. 3). Step B then is the actual logistics model, where the choice of transport chain from P to C and that of shipment size are made for each firm-to-firm flow by minimizing the logistics costs. Because the assignment to the networks needs to take place at the aggregate level for OD flows, the transport chains from step B are decomposed into OD movements and aggregated back to flows between zone pairs (step C), also taking into account empty return flows.

The logistics costs comprise:

- Order cost
- Distance-based transport cost
- Time-based transport cost
- Loading at sender; unloading at receiver
- Transfer at terminal
- Deterioration and damage
- Capital costs in transit (time)
- Inventory and capital cost at receiver
- Safety stock cost

Other solutions than the ADA model to introduce more aspects of logistics into the four-step model in national freight transport planning have been developed. These include:

- The aggregate, but very detailed in terms of sectors and commodities, model SMILE+ (Tavasszy et al., 1998) that was developed as a national freight transport model for The Netherlands in the late 1990s (the current Dutch national freight transport model BasGoed took a step back to the four-step structure, because the more sophisticated model became hard to maintain).
- The aggregate EUNET model that was developed for the United Kingdom that includes choice of distribution structure and multimodal transport chains.
- The disaggregate FAME model (Samimi et al., 2010) developed for the United States, and is rather similar in structure to the ADA model but includes a disaggregate model for the choice of supplier by the receiver of the goods (to predict the PC flows), so moving toward a disaggregate-disaggregate-aggregate (DDA) model.

Modeling Freight Generation and Distribution

Model types at the zone-to-zone level that can be used for the generation and distribution steps, or for the PC step of ADA-type model systems, are:

- gravity models;
- input–output (I/O) models; and
- spatial computable general equilibrium (SCGE) models.

A simpler approach specifically for generation is the use of sector-specific trip rate tables (or for tons of freight). Zonal trip rates for production and attraction are usually derived from classifying cross-sectional data on transport volumes to/from each zone in the area under investigation (or another similar area) into a number of homogeneous zone types.

Gravity-based models predict the flow of goods between two zones as a function of production and attraction of these two zones (e.g., represented by employment in specific sectors) and transport resistance between the two zones. For the estimation of these models, trade statistics (PC level) or transport statistics (OD level) are needed. The PC level is most appropriate for a gravity model, since this relates to the zones where these goods were actually produced and consumed (including further processing). A gravity model on transport statistics is less appropriate, since, for multimodal transport chains, the starting and ending points from the transport data may not be the actual locations that caused the goods flow, but just transshipment locations.

I/O tables describe, in money units, what each sector of the economy (e.g., steel manufacturing) delivers to the other sectors of the economy (e.g., car manufacturing). The final demand by consumers, imports, and exports is also included in these I/O tables. National I/O tables have been developed for many countries, usually by the central statistical office of the country (e.g., Statistics Sweden). I/O models are macroeconomic models that use the production structure links between sectors as described by the I/O

tables to predict how a change in demand or production or consumption in some sector influences the other sectors. The multiregional or spatial input–output (MRIO) table is a special form of I/O table, which not only includes deliveries between sectors, but also between sectors in different regions (interregional trade flows). Not all countries have up-to-date national I/O tables, and recent multiregional I/O data are only available for a few countries. An I/O model that takes account of the spatial structure of the links between sectors (MRIO model) can be used to predict trade flows between zones. In doing this, some I/O models also take transport distance, time, and/or costs between the zones into account.

Another option for production and attraction is the computable general equilibrium (CGE) model that establishes equilibrium in several related markets (not only transport, but also goods markets, labor markets, and land markets). They require similar data as I/O models: I/O tables or Make and Use tables from the national accounts data, preferably multiregional (otherwise, one might carry out a rationalization). CGE models in economics (not focusing on transport) often include economic issues that are not handled in transport models, such as type of competition and economies of scale. Spatial CGE (SCGE) models have been developed more recently, and could become operational models for practical (inter)national and regional forecasting and evaluation in years to come.

In order to make distribution models dependent on transport costs and time between zones, one needs to include time and distance data from transport network skims (possibly combined with cost functions), or accessibility indicators (such as logsums) from mode choice models.

There are hardly any disaggregate models for generation and distribution in freight transport.

Modeling Mode Choice and Route Choice in Freight Transport

Aggregate mode choice models can be estimated on transport statistics data by mode, which are available in many countries. For the estimation of disaggregate mode choice models, one needs shipper surveys, stated preference surveys with mode choice experiments or consignment bill data. Only few countries have such data sources available to researchers. Shipper surveys can also be used for models of shipment size or for joint models of mode and shipment size.

In the ADA models and other model systems where generation and distribution are carried out at the PC level, the corresponding mode choice component is a transport chain choice model. The transport chains in this model can be unimodal or multimodal. The limited direct observations that we have of transport chains come from disaggregate shipper surveys (including commodity flow surveys).

Both for a mode choice and for a transport chain choice model, one also needs network data (time and cost by mode) and cost functions. For a transport chain choice model, data on the locations of terminals for transshipment is also required.

Network assignment models typically do not use information on observed choices or market shares, but use a deterministic rule to assign vehicles to a shortest path. The same modeling philosophy that is routinely used in network assignment can also be used for other choices where information on observed choices is missing. In the absence of information about transport chains, one might use a deterministic model that predicts the transport chain choice on the basis of the minimization of the full logistics costs. However, the outcomes of this are normative and not necessarily realistic. The latter problem can be reduced by a calibration of the model to other data, such as mode shares at the OD level from transport statistics.

A number of freight transport models at the national or international level use a simultaneous assignment to modes and routes: multimodal assignment. This requires that the networks of the various modes are connected to each other to represent the multimodal terminals: the nodes where transshipments between different modes can take place. The existing multimodal assignment models in freight all work at the aggregate level.

Short Overview of National Freight Transport Models

In **Table 1**, we list the currently used model approaches in national freight transport modeling and provide some examples from practice for each approach (de Jong et al., 2012). The same approaches are not only used for national models, but also for international models, such as transport models systems for Europe as a whole (Transtools1, 2, 3, TRIMODE, LOGIS) or world models (Worldnet) and for states/provinces and metropolitan regions within larger countries (e.g., the MetroScan model for the

Table 1 Practical examples of different approaches in national freight transport modeling

<i>Model approach</i>	<i>Model</i>
Aggregate four-step	Dutch national model (BasGoed), Flanders strategic model, France (MODEV), Great Britain freight model (GBFM)
Aggregate multimodal assignment	Belgian model for the Walloon region (NODUS)
Aggregate model with logistics	Previous Dutch national model (SMILE+), EUNET model for the United Kingdom
Partly disaggregate, optimization	National models of Sweden, Norway, and Denmark, Model for Mobility Masterplan Flanders (= the ADA family)
Partly disaggregate, statistically estimated on observed data	German Federal Model, US national model FAME, US national freight model for FHWA (prototype under development), Danish model for Fehmarn Belt corridor, prototype stochastic national model for Sweden, and planned national model for Austria

Sydney area or the models for Alberta or Toronto in Canada, or Oregon or Chicago in the United States). The category that is used most in practice is the aggregate four-step model. Within the partly disaggregate model systems, there are models that use a deterministic minimization of logistics costs to find the transport chains and shipment sizes, and there are models that are statistically estimated on data from a disaggregate data source such as a commodity flow survey or a stated preference survey.

Conclusions

National freight transport models have been used for practical transport planning by the national transport authorities at least since the late 1980s/early 1990s, for scanning the future under various exogenous scenarios and for providing the transport inputs in the appraisal of transport projects. Since these early models, several new developments have taken place in freight transport modeling at the national and related spatial scales. Many of these new developments were related to attempts to include more logistics choices in the modeling framework. In spite of these new developments, the approaches that were used in the earliest national models (aggregate four-step freight transport models) are still the most common methods in practice. The main reasons for this seem to be a lack of data (especially on transport chains and, more generally, disaggregate data) and high costs of new data collection. It is hoped that new electronic data collection technologies, in combination with older survey methods, can lead to improvements in this area.

Introduction

There was a time when freight, whether moving in cities or outside, was the purview of logistics and transport economics. No more. Freight is a major component of urban transport flows. It impacts and interacts with passenger transport, generates many externalities, and influences the changing spatial organization of cities. Freight demand is largely an urban demand: producers and consumers are concentrated in metropolitan areas, the economic engines of the global economy. As the global economy has become more liberalized, supply chains have expanded, and regional networks of production, tied together via transport, have emerged. Large cities are the major nodes in these regional networks.

At the same time, the growth in consumption associated with rising per capita income generates more freight flows in getting goods to and from local markets. Online shopping and instant deliveries only add to this growth. As a result of these trends, urban freight demand has generated interest within urban planning, geography and civil engineering, in addition to economics and logistics. This new interdisciplinary field seeks to understand the dynamics of urban freight, its relationship with urban spatial structure, and to generate effective strategies for managing urban freight and increasing its sustainability.

This chapter provides an introduction and overview of urban freight. First, the major impacts of freight are discussed, including congestion, air pollution, and safety. Second, urban freight is categorized into two types: trade related and local. Third, two trends affecting urban freight are described: the changing spatial organization of warehousing and distribution, and the rise of e-commerce. Fourth, an overview of freight mitigation is presented. The chapter closes with some considerations on longer term trends that may bring further changes to urban freight.

The Urban Freight Problem

Freight generates many problems for metropolitan areas, yet the efficient movement of freight is essential for economic and social well-being.

Air Pollution and GHG Emissions

Freight (primarily trucks) accounts for a significant share of air pollution and GHG emissions. Specific contributions vary by country, as they depend on the age and technology of the fleet, as well as the total volume of emissions. In the United States, the transport sector accounts for nearly 60% of NOX and 22% of VOC, the precursors to smog and ozone. Trucks account for about one-

Figure 1 Annual PM 2.5 emissions and combination truck VMT. Source: Calculated by author from USDOT Bureau of Transportation Statistics data.

third of the transport share. The regulation of engines and fuels has resulted in lower emission rates. To date, declining emissions rates have offset the growth of truck VMT (vehicle miles traveled). For example, [Fig. 1](#) shows the annual estimated PM_{2.5} emissions and combination truck VMT from 2000 to 2017. The increase from 2006 to 2007 is due to a change in the method used to calculate VMT.

The US transport sector accounts for 29% of GHG emissions. Within the on-road transport sector, freight accounts for 23% of all GHGs. As other sectors reduce GHGs, the transport share is increasing. The contribution of trucks is increasing more than that of other transport modes. From 1990 to 2017, the total GHG transport sector emissions increased by 22%, but truck emissions increased almost 90% ([US EPA, 2019](#)). The truck share is increasing due to the growth in overall freight volumes, the continuing trend toward using faster modes, rising congestion, and the technology challenges of developing cleaner medium and heavy duty vehicles.

Congestion

Freight contributes disproportionately to congestion. Large trucks are more difficult to maneuver and are slow to accelerate and decelerate, adding delays to the surrounding auto and bus traffic. In city cores, limited parking and loading facilities result in illegal parking (in bicycle lanes or at bus stops, or double parking in the roadway).

It is difficult to identify the contribution of freight activity to the overall level of congestion due to data limitations. [Giuliano et al. \(2018\)](#) developed the concept of “freight impact area” to identify road segments with high levels of freight-related congestion. Applying the concept to the Los Angeles region, they identified and ranked freight impact areas based on total peak period congestion and the share of trucks in the traffic flow. The top 15 freight impact areas were located along major corridors connecting intermodal facilities, industrial, and warehouse zones. The top 15 together account for 53,615 h of vehicle delay each PM peak period, or about 14 million hours per year.

Conflicts and Safety

Freight conflicts with passenger transport for limited road and sidewalk capacity, creating safety hazards. As cities become more dense and pedestrianized, safety hazards increase. Freight is known to get delivered no matter the circumstances, whether it requires parking on a sidewalk, double parking, or blocking a bike lane or transit stop. Local safety data is not widely available. [Table 1](#) gives the number and share of deaths of motorcyclists, bicyclists, and pedestrians from crashes involving large trucks from 2000 to 2018 in the United States. The drop in fatalities in 2010 is explained by the Great Recession. The total number of deaths has decreased since 2000, but deaths of motorcyclists, bicyclists, and pedestrians have increased. Consequently, these mode users represent an increasing share of all fatalities. This trend is an indicator of more urban truck traffic, where conflicts with bicyclists and pedestrians are more likely. A recent study examined crashes by location—urban/nonurban, on or off interstate highway—and found that the share of freight-related crashes with nonfatal injuries taking place in urban areas off interstates is increasing, another indicator of growing freight safety problems in cities ([McDonald et al., 2019](#)).

Table 1 Deaths of motorcyclists, bicyclists and pedestrians from crashes involving large trucks, 2000–18

<i>Year</i>	<i>No. of deaths, motorcyclist, bicyclist, pedestrian</i>	<i>No. of deaths, all</i>	<i>Percent motorcyclist, bicyclist, pedestrian</i>
2000	490	5173	9.5
2005	595	5049	11.8
2010	445	3418	13.0
2015	568	3876	14.6
2018	619	4136	15.0

Two Types of Urban Freight Flows

Metropolitan freight activity may be described in terms of two main types: freight related to local supply or demand, and freight related to national or international trade.

Local Freight Demand

Freight related to local supply and demand is often termed “last-mile” freight: local supply and demand is typically the first or last move in complex regional and global supply chains. Local freight activity includes delivery or pickup of imports/exports, intra-metropolitan trade of commodities (local production and consumption), construction, waste removal, and shipments between warehouse and distribution facilities, retail facilities, and homes and business.

Local freight demand is a function of population and employment; as metropolitan areas grow, so does local freight demand. It is also a function of per capita income. Thus, as metropolitan areas become richer, the demand for local goods and services increases. Other trends are accelerating local freight activity, notably the rise of e-commerce and higher velocity supply chains. E-commerce, or online shopping, spreads freight demand throughout the city, leading to more freight deliveries. Higher velocity supply chains mean less inventory and more frequent deliveries. In city cores, restaurants, retail shops, offices, and even apartment dwellers minimize storage space in response to high rents.

Trade-Related Freight Demand

Freight related to national or international trade is a function of the integration of the global economy, itself a result of advances in information and telecommunication technology and trade liberalization policies (Dicken, 2007). Production supply chains have become more complex as producers seek out comparative advantage opportunities around the world. This process has resulted in consistent growth in cross-border trade for the last several decades. For example, total imports grew by 92% from 2000 to 2017 while total exports grew by 98% in the United States (US Census, 2018).

Cities that serve as trade nodes have an additional layer of freight and logistics demand, because they serve both local and nonlocal supply and demand. Table 1 gives an example from California. Los Angeles and San Francisco are well-known international trade centers, while Sacramento and San Diego are not. Table 2 gives domestic and international commodity flows in US dollars per capita. Domestic flows have a narrow range, from about 35,000 to 41,000. In contrast, international flows are much higher for Los Angeles and San Francisco. Although international flow is about half as much as domestic flows for these cities, the volume of trade adds significantly to overall freight demand. This added demand implies more congestion, air pollution, and goods movement facilities.

Two Major Trends

Urban freight is dynamic; supply chains change constantly in response to prices and consumer demand. In this section, two changes are described that are affecting both the volume of urban freight flows and their spatial organization.

Table 2 Commodity flow per capita by Freight Analysis Framework area

<i>Metro area</i>	<i>Domestic flow/capita (US\$)</i>	<i>International flow/capita (US\$)</i>
Los Angeles	35,331	17,036
San Francisco	37,725	18,196
San Diego	37,564	4992
Sacramento	41,013	3450

Figure 2 Warehouse location by year built, Los Angeles region. Source: *Giuliano and Yuan (2017)*.

Spatial Organization of Warehousing and Distribution

Significant changes have taken place in the warehousing industry during the last decade. First, the growth of warehousing and distribution activity has been greater than that of the general economy (*Giuliano and Kang, 2018*). Second, warehousing facilities are increasingly specialized, for example, in transshipping, packaging, or inventory management (*Akman and Baynal, 2014*). They serve a wide range of customers, including 3PL logistics providers, trucking and freight forwarders. Third, warehousing facilities serve more geographically dispersed markets (*Hess and Rodrigue, 2004*) as economies of scale intensify within the industry. Fourth, warehouses provide more frequent deliveries as retail businesses seek to reduce inventory and save on rent costs. Finally, the scale of warehousing and distribution has increased due to automation and high-volume product flows. Although increases in e-commerce and consumer demand for instant deliveries are creating demand for close-in distribution or fulfillment centers, these trends have not reduced demand for largescale warehousing. Rather, distribution chains are changing.

The result of increased warehousing activity, scale, and demand has been the decentralization of warehouse and distribution facilities, as documented by studies of several large metropolitan areas in the United States, Europe, and Japan. *Fig. 2* is an example from the Los Angeles region. Warehouses are color coded by year built. It can be seen that the newest facilities are generally located far to the east of the urban core.

One US study of warehouse location from 2003 to 2013 in the 48 largest metropolitan areas revealed the following: (1) warehousing decentralized by about 1 mile, measured as the average distance of all warehouses to the CBD; (2) large warehouses decentralized more than smaller warehouses, and (3) large warehouses decentralized more in the largest metropolitan areas. Decentralization is largely a function of land values. The study used the population density gradient as a proxy for land value, and found that decentralization is negatively associated with the steepness of the gradient and positively associated with peak density (*Kang, 2017*).

The shift of warehousing and distribution activity to larger facilities far from the urban core suggests more concentrated freight traffic as the scale of distribution increases and distribution networks become larger. Spatial clusters of distribution facilities add to this concentration.

The emergence of clusters of large warehouses (over 1 million square feet) has led to questions of environmental justice. Warehouses are major truck trip generators and, hence, major sources of air pollution. Truck traffic generates noise and pavement damage as well as traffic safety threats. An extreme example of warehouse development is the Highland Fairview Logistics Park in Moreno Valley, California. It is the home of the Sketchers warehouse, a 2 million square foot facility that is over ½ mile in length (see *Fig. 3*). It is part of a larger World Logistics Center that is proposing 40 million square feet of warehouses.

The environmental justice question is whether warehouses are disproportionately located near low income or minority neighborhoods. There are three arguments for why this may be the case. First, warehouse developers seek places with low land prices and access to low wage labor, and such places are often where low income or minority households reside. Second, disadvantaged

Figure 3 Sketchers warehouse, Moreno Valley, California. *Source: Laetitia Dablanc photo collection, by permission.*

populations have less political power, and hence less capacity to resist locally undesirable land uses. Third, discrimination in housing markets constrains location choice, especially for poor minority households.

A study of four metro areas in California reveals a more complex relationship: warehousing location is associated with medium and low income minority neighborhoods in Los Angeles, San Francisco, and Sacramento, and only with medium income minority neighborhoods in San Diego (Giuliano and Yuan, 2017). A possible explanation for these findings is that low income neighborhoods are not necessarily located in areas with low land prices and adequate transport access required by large facilities. This work was extended to test causality: do households follow warehouses as they search for cheaper housing, or do warehouses follow households as they search for cheaper land? Results showed the latter, suggesting that warehouse location is an environmental justice problem in the four California metro areas (Yuan, 2018).

The Rise of E-Commerce

E-commerce is defined as any type of consumption that takes place via an online platform. The most common type of e-commerce is online shopping; consumers order and pay online, and the goods are delivered to the consumer's residence. There are variations: the consumer may order online and pick up at a retail establishment, or at a local locker facility. E-commerce includes all types of consumption, from meal deliveries to cat litter to furniture. The emergence of online shopping has transformed where and how goods are produced, distributed and sold, and how consumers make shopping, as well as shopping travel, decisions (Mokhtarian, 2004).

The rise in e-commerce has been rapid. In the United States, the market share of online shopping has increased from about 3.7% in 2008 to 9.5% in 2018. The annual rate of growth of online shopping sales has been around 11%–13% since 2011, much greater than the rates for total retail sales, 3%–4% (US Census, 2019). Global online sales as of 2018 are estimated to be about \$2.5 trillion and account for about 9% of all retail sales. Some countries have much higher shares of e-shopping: 18% for the United Kingdom and 16.6% for China as of 2018 (Investp, 2020). E-shopping is expected to continue to grow, with great uncertainty with regard to when the rate of growth will slow.

E-commerce is also changing rapidly. The variety of goods available continues to grow, and some new products have emerged, such as ingredients and instructions for home prepared meals (e.g., Blue Apron). Speed of delivery is also increasing. Some firms now offer "instant deliveries" (within 2 h), and one day delivery is now routine in many metropolitan areas. The growth of e-commerce is illustrated in Fig. 4, which shows trends in mail volume and package volume in billions of units. Mail volume has declined consistently from 2007, while parcel volume has increased. For the same period, the total number of parcels increased from 7.2 to 17.8 billion, a 140% increase.

E-shopping has many impacts on cities. First, e-shopping affects travel behavior. If shoppers simply substitute an online purchase for an in-store purchase, travel is reduced. However, shoppers may behave in many different ways. Shoppers may inspect merchandise in stores and then purchase online, or the reverse. Shoppers may shop more overall because of the convenience of online purchases. Even if shoppers make fewer shopping trips, they may use the extra time to travel for other purposes. The mode of travel is also an important consideration. If the trip to the store is made by walking or biking, there is no environmental benefit, even if it is

Figure 4 USPS mail, parcels carried by major carriers, US, 2004–18. Source: Rodrigue, J.-P., 2020. *The Geography of Transport Systems*, fifth ed. Routledge, London. Available from: https://transportgeography.org/?page_id=1698.

fully replaced by online shopping. At this time there is insufficient evidence to draw any conclusions on travel behavior impacts (Cao, 2009).

Second, e-shopping affects goods distribution. E-commerce requires delivery to a residence or local common pickup point. Small-scale deliveries (small packages in small trucks) are less efficient than the large scale deliveries made to retail establishments. Although e-shopping eliminates at least some large-scale deliveries (due to the loss of in-store business), these losses will be more than offset by the added truck travel generated by small scale deliveries. Efficiency of freight deliveries is further reduced by the rate of failed local deliveries and the higher rate of returns associated with online shopping. The outcome is increased truck VMT (Rotem-Mindali and Weltevreden, 2013).

One day and instant deliveries also affect the distribution supply chain. In order to offer one day or less delivery, retailers must have enough inventory and be close enough to consumers to be able to fulfill, package, and deliver an order in a matter of hours. Technology and predictive analytics help to stock fulfillment centers with goods in anticipation of orders, yet the entire system depends on fast transport, from warehouse to fulfillment center to customer. In highly congested metropolitan areas, these facilities must locate closer to customers.

This leads to the third impact on cities: the changing demand for retail and industrial space in metropolitan areas. One of the most visible impacts of changing shopping behavior in the United States is the failure of shopping malls. From 2012 to 2017 nearly 20% of regional malls were closed down (ICSC, 2013, 2017). E-shopping is a contributing factor. The traditional mall is organized around anchor stores—the major department store chains (e.g., Macy’s, Sears)—with smaller stores between. The anchor stores provide the customers for the smaller specialty stores. As department stores consolidated and closed stores, the traditional structure was no longer viable, and the weaker malls failed. The trend continues, and it is expected that 20%–25% of existing malls will close by 2022 (Credit Suisse, 2018). In other countries, the growth in online shopping is associated with a decline in in-store shopping; hence generating declining demand for retail space.

At the same time, the continued growth of online shopping and instant deliveries is generating increased demand for in-city warehouse and distribution facilities, despite higher rent and operating costs. Amazon and other online retailers are engaging in adaptive re-use to develop local instant delivery networks. Examples include the conversion of a printing facility in Barcelona and a parking structure in Paris (see Fig. 5). In the United States, failed malls have become distribution centers, and retailers such as Target are using their extra space as local micro-distribution centers and pick up points. The transportation implications of these shifts are significant: more truck traffic in local residential and commercial areas, truck traffic replacing auto traffic, and more complex distribution chains.

E-shopping is having additional impacts on the built environment. For example, the traditional design of an apartment building includes a reception area and tenant mailboxes. There are no provisions for large numbers of package deliveries, which results in reception areas becoming de facto parcel storage areas. New apartments are being built with parcel storage areas and communications systems to inform tenants of deliveries. In an effort to reduce the cost of home deliveries, Amazon and others are establishing “pickup points” and lockers to consolidate home deliveries. Pickup points are common in many countries, including France and Korea. They are often located at transit stations so that shoppers may pick up parcels on the way home from work or other activities, but also may be located in convenience stores, banks, or other places.

The Problem of Free Shipping

One of the motivators of the growth in e-shopping is free delivery. Although consumers value the convenience of online shopping, they are also price sensitive. Paying for shipping makes online purchase less competitive with the in-store option. Online retailers

Figure 5 Amazon fulfillment center, Barcelona. *Source: Laetitia Dablanc photo collection, with permission.*

have responded by offering free shipping, first for standard shipping (3 days or more), then for one or two day shipping, and now often for instant shipping. Rather than competing on product price, online retailers are competing on free shipping.

Free shipping is of course not free. It is a subsidy to consumers; the delivered product is priced below cost. As with any other good that is priced below cost, more will be consumed than economically optimal. Without free shipping, at least some online sales would be diverted to in-store purchases. In addition, free shipping is an incentive for consumers to be wasteful. Under most circumstances, a consumer would not travel to a store for one small item, for example, a pair of socks. Rather, the trip would be made when the total purchase is worth the trip. With free shipping, there is no penalty for single item purchases. The consumer has no reason to bundle purchases, or to delay their satisfaction in obtaining the item. The fragmentation of purchases adds more inefficiency to freight deliveries, generating more truck traffic and pollution.

Strategies for Managing Urban Freight

Cities around the world are employing a vast array of strategies to mitigate negative impacts and better manage freight flows. It is not possible to provide a comprehensive discussion of the many strategies considered or employed around the world. This section provides a brief overview, along with a few specific examples.

Managing Trade-Related Freight

Strategies for managing trade-related freight are summarized in [Table 3](#). Strategies are organized into four categories, and examples of each are presented. Infrastructure strategies tend to be effective, because they add some form of freight capacity to the system. However, high costs, the lack of available space in urban areas and local environmental impacts often preclude such strategies. For example, truck-only lanes would require highway expansion and a design that would prevent conflicts between trucks and passenger vehicles. Corridors most in need of truck lanes are located in dense urban areas, where the taking of additional land is most

Table 3 Strategies for trade-related freight

Type of strategy	Infrastructure	Efficiency	Emissions	Pricing
Examples	Truck only lanes Truck bypass facilities Railroad grade separations Added highway capacity On-dock rail Inland ports	Advanced freight traffic management systems Integrated freight information systems Freight priority traffic management Cargo matching services Smart truck parking Terminal appointment systems Truck platoons	Low emission fuel standards Zero and near zero emission trucks Low carbon fuel standard Mode shifts	Truck and passenger VMT tax Congestion tolls Truck lane tolls Port cargo or gate tolls Carbon tax Carbon cap and trade system

problematic. In addition, truck only lanes would attract more truck traffic to the corridor, increasing the environmental burden on the nearby population.

Efficiency improvements seek to take advantage of advancements in information and communication technologies. Connected vehicle systems make it possible to manage traffic in real time, increasing safety and system efficiency. Efficiency improvements are attractive because many have relatively low cost and increase the productivity of the existing infrastructure. Innovation is taking place in both public and private sectors. Governments are developing various types of freight traffic management strategies such as route guidance or dynamic traffic signal operations. The private sector is developing platform-based services that seek to efficiently match buyers and sellers. As connected and automated vehicle technology continues to develop, trucking is expected to be among the early adopters. As of 2020, semi-automated trucks are being operated in pilot studies along the I-10 corridor from Arizona to Texas, and truck platoons have been demonstrated in several US states.

By far, the most effective emissions reduction strategy to date has been regulation based on emissions and fuel consumption standards. In the United States, the first national emissions standards were established in 1973. Emissions of four criteria pollutants declined by half or more by 2015, despite vehicle travel tripling over the same period (US EPA, 2018). Zero emission technology is currently limited to battery electric trucks. Hydrogen fuel cell technology has promise, but remains experimental. Battery technology is improving, making possible some penetration in the medium duty market. Heavy duty trucks remain a challenge due to the limited range and long charging times for batteries large enough to haul a heavy load.

Pricing is the most effective strategy for solving externality problems of all types, yet it remains politically difficult to implement. Pricing provides clear incentives for behavioral change and provides revenue for infrastructure investment. For example, a truck VMT tax could be used to fund highway rehabilitation, or to subsidize the purchase of electric trucks.

Text box reference: Zhao, Y., Ioannou, P., 2019. A co-simulation, optimization, control approach for traffic light control with truck priority. Annu. Rev. Control 48, 283–291.

Intelligent Traffic Priority for Trucks

Could we reduce traffic delay for all vehicles if we give traffic priority to trucks under some circumstances? It is well known that heavy trucks have disproportionate impacts on traffic due to their large size, slow braking and acceleration, and wide turning radius. Traffic signal timing and control is based on the performance characteristics of passenger vehicles. In a dynamic system, signals are timed to minimize delay based on passenger vehicle parameters. However, every time a truck stops at a signal, the following vehicles are slowed down by the slow acceleration of the truck when the light turns green, and it takes more time for all the waiting traffic to clear the intersection. If the truck were able to move through the intersection without stopping, the delays behind the truck would not occur.

Researchers have developed methods to manage traffic signals in real-time, giving priority to trucks when doing so leads to overall reductions in delay. Simply setting a principle of giving trucks signal priority is not sufficient, as a net reduction in delay depends on traffic patterns and composition. These methods were tested via simulation modeling using traffic data in an area around the ports of Los Angeles and Long Beach. Results show that truck priority results in reduced delay for all travelers. The reduction in delay also reduces truck emissions and energy consumption. Vehicle-infrastructure technology will allow for such customized versions of traffic management.

Managing Local Freight Demand

Strategies for managing local freight have an added category, regulation, as regulation plays such a critical role in urban freight. Infrastructure strategies are much smaller in scale, reflecting the more local focus of last-mile pickups and deliveries (see Table 4). Truck lanes may be demarcated to clearly identify major truck routes through the city and prevent conflicts with other traffic. Adequate parking and loading facilities reduce parking violations. Street and sidewalk design can be used to accommodate truck traffic where needed, while preserving space for nonmotorized transport. In-city consolidation centers facilitate more full truck movements.

There are many options for efficiency improvements beyond advanced traffic management. Deliveries to retail establishments or warehouses can be shifted to evening hours, moving truck traffic out of crowded daytime hours. Pickup points reduce the number of residential deliveries.

Table 4 Strategies for managing local freight demand

Type of strategy	Infrastructure	Efficiency	Emissions	Pricing	Regulation
Examples	Truck lanes Truck parking and loading zones Flush curbs Sidewalk cutouts Consolidation centers	Advanced traffic management systems Freight priority traffic management Off hour deliveries Lockers and pickup points	Zero and near zero emission trucks Cargo bikes Low emission zones	Cordon tolls Loading zone and parking fees Licenses	Truck size and weight restrictions Parking enforcement On-site loading docks

Text box references: Holguín-Veras et al., 2018; Sanchez-Díaz et al., 2016.

Off-Hour Deliveries

A major source of urban congestion is commercial deliveries to restaurants, stores, hotels, etc. Traditionally, these deliveries take place during regular business hours (during the day) so that labor is available to receive the shipments. Shifting these deliveries to night time hours, termed off-hours deliveries (OHD), would generate many benefits. Reduced daytime truck traffic would reduce congestion, truck emissions, and energy consumption. Vehicles and delivery infrastructure would be more efficiently used, and delivery times would be less uncertain. Given the potential benefits, it is logical to ask why OHD is not widely practiced. The main reason is cost: receivers must employ a crew for an additional shift in order to accept the deliveries. Another option is to deliver to a secure location, with the truck driver completing the delivery. However, receivers (cargo owners) may be reticent to trust others to safely access and egress facilities and to forego checking the order before acceptance. Other challenges include noise impacts on neighbors, and desire of drivers to work the daytime shift.

The New York State Department of Transportation funded a large, multiyear OHD pilot project in New York City in order to determine how a successful OHD program could be implemented. Years of research revealed that with the right incentives (subsidies to offset added labor costs, shipping discounts, and public recognition) businesses were willing to participate. By 2016 there were 400 participating businesses. The New York City pilot demonstrated that OHD benefits are widespread. Reduced daytime truck traffic and associated reduced congestion generates benefits for both passenger and freight traffic.

The New York City pilot has led to implementation of OHD programs around the world. Sao Paulo has the largest program, with over 700 participants. London, Copenhagen, Stockholm, as well as Bogota, Medellin, and Cartagena (Columbia) have operating OHD programs as of 2020.

Pollution impacts are of particular concern in cities, as human exposure is concentrated. Thus, extensive experimentation is taking place with zero emission vehicles. In very dense urban areas, cargo bikes (electric powered bicycles with a cargo hold) may deliver the last few meters. Low-emission zones have been established in several cities. For example, Paris requires heavy duty trucks to be registered as meeting Euro V standards in order to gain access between 8 AM and 8 PM on weekdays. In California, several zero and near zero emission heavy duty truck demonstration projects are taking place to promote the use of ZE trucks in short haul service. California is also developing a “ZEV mandate” for trucks that will require truck manufacturers to sell a minimum percent of ZE trucks as part of new truck sales.

Pricing is also relevant at the local level. Cordon tolls began in Singapore in 1975 in order to manage traffic in the central core. London launched cordon tolls in 2003 in response to debilitating traffic congestion, and has since expanded the system to incentivize use of low emission trucks in the central area. In contrast to the Paris example, London uses pricing to promote cleaner trucks. The London low emission zone (LEZ) was introduced in 2015 and encompasses all of Greater London. Trucks must meet a specified Euro standard in order to enter the zone without paying a fee. The standard is graduated. Currently, the standard is Euro IV; in October 2020 trucks will have to meet Euro VI.

Local governments have regulatory authority that can be used to manage freight. Building permits can require construction of on-site loading docks so that the use of curb space is reduced. Codes can require ample parcel or inventory storage space.

Conclusion

This chapter has provided an overview of a relatively new field of transport research. It is a field that is changing rapidly as global economics and politics affect trade patterns, as technology changes transportation and as consumer behavior evolves to take advantage of more convenient travel and consumption alternatives. The topic is concluded with some observations on current emerging trends that may bring additional changes to urban freight.

Global Trade: Might Ever Greater Integration Be Coming to an End?

Global trade has expanded as a result of technology and trade policy. It is not inevitable that this expansion will continue. First, some countries are moving away from multilateral trade as they adopt nationalist political agendas. The United States and Great Britain are notable examples of this trend. Second, aggressive efforts to manage climate change will require major changes in the transport sector. Through a carbon tax, cap and trade, or strict regulation, transport costs will rise, and the advantage of off-shore production will decline. Public perceptions may also be changing. Indicators include the emergence of the “flight shame” movement in Europe and the Locavore movement in the United States, which urges people to eat locally sourced foods. These factors may shrink the geographic reach of supply chains, possibly reducing trade-related urban freight activity.

Might the Consumption of Material Goods Decline?

As noted earlier in the chapter, freight demand is largely a function of population and per capita income. However, if the environmental cost of disposable or lightly used goods becomes more widely understood, it is possible that consumption per capita would decrease. The early stages of reducing waste are evident in the widespread bans on plastic bags, disposable cups, etc. Less evident but growing are movements away from “fast fashion”—buying garments for a few uses and then replacing them with the

newest style. Fast fashion consumes a lot of energy in producing and transporting the garments and then generates more energy consumption as the disposed garments join the waste stream. There is an emerging backlash against fast fashion, especially from Generation Z, which is particularly attuned to global climate change. In addition, the sharing economy continues to grow, with more apps available every year for trading or sharing clothing, tools, furniture, and much more. These apps increase the efficiency of using material goods and hence can reduce overall demand. Reduced demand may or may not reduce freight flows, as sharing or swapping implies transport.

While these potential changes would affect patterns of urban freight, it seems unlikely that freight volumes would be significantly reduced. Peer-to-peer sharing further fragments shipments. Shorter supply chains do not imply less impacts on cities. Urban freight will continue to be in need of innovative solutions to increase the sustainability of the world's metropolitan areas.

Introduction

Cities around the world are changing rapidly. Many are growing and this trend seems set to continue with over half the world's population already living in urban areas. Much attention has focused on the growth of some of the largest cities—those with a population over 10 million—referred to as mega-cities. However, many smaller cities are also growing. The growth and the scale of cities mean that urban logistics has become more important and relevant to public authority policy making. Urban logistics has in many cases responded very effectively to the requirements of modern urban economies. However, it is a major contributor to environmental impacts, particularly to local air pollution and noise and, as a result, has an important impact on the health of the most vulnerable residents of cities. This rise in importance and the initiatives that can be taken in urban logistics provides the focus for this chapter.

Urban freight transport and logistics involves the delivery and collection of goods and provision of services in towns and cities. It also includes activities such as goods storage and inventory management, waste handling, office and household removals and home delivery services (Allen et al., 2015). Scope and definitions can be important because they have implications for the policies developed by those responsible for transport and related activities in cities and metropolitan areas. A key change has been the growing tendency to include the last-mile deliveries to final consumers associated with e-commerce within the scope of urban freight transport and urban logistics. A report by the RPA (Barone and Roach, 2016) noted that different geographical scales could be considered in urban freight and logistics activities. At the wider or regional scale, the commodities travelling into and out of a metropolitan area need to be addressed. At the more local level, there are those flows that remain within a metropolitan area or perhaps a smaller part of such an area.

Hicks (1977, p.100) noted that: "any urban area depends for its existence on a massive flow of commodities into, out of, and within its boundaries. Yet the transport of goods remains a forgotten aspect of urban transportation study."

At the time, few would have disagreed with Hicks that this important activity had received relatively limited attention from researchers. However, there has been a major growth in research into urban freight, encouraged by the increased attention that has been focused on wider logistics activities. The extra attention has been strongly influenced by the growing awareness and concern about the local and global environmental impact of transport and the implications for the economic vitality of cities caused by congestion problems.

Over the past 40 years, the range of commodities, the scale and the complexity of the flows has increased. For example, during the past 10 years the growth in e-commerce means that many products now go direct from a seller or supplier to the end-customer. These changes in the routing of products has led to a significant rise in the use of small vehicles, such as vans and cargo cycles, in many cities. Although there have been major changes in the volume and types of commodity moving within cities it has, in most cases, been difficult to change the infrastructure to accommodate these new patterns.

A major challenge for improving urban logistics lies in the nature of the activities. Decisions about freight movements and truck operations lie almost entirely in the hands of the private sector. However, the regulatory and legal questions about freight movements in cities are addressed by public authorities—for example, city councils or metropolitan authorities. Many cities have a powerful political figure, such as a mayor, who takes overall responsibility for transport and other strategies in the development of the city. The political level typically relies on professional policy makers and technical managers to develop policy and manage transport and traffic in the city. Long-term land-use planning is also controlled by public authorities with considerable variation in the detailed legal powers governing these actions in different countries and indeed sometimes between cities in the same country. In addition, urban areas vary substantially in terms of factors including their geographical and physical size, population density, economic composition, land-use patterns, transport infrastructure, and street layouts. All the above makes for a complicated

commercial, technical, social, and political landscape within which urban logistics activities take place. This in turn has made it difficult to find simple solutions to urban logistics and freight problems that can be readily scaled up and transferred.

Urban logistics plays an important economic role in cities and its efficiency or otherwise has implications including:

- the effect of logistics and supply chain costs on the cost of commodities consumed in a city or metropolitan region;
- the fundamental importance of urban logistics in sustaining urban lifestyles;
- the role urban logistics plays in the service, retail, and trading activities which are essential for wealth generation in cities.

At the same time there has been a major focus on the problems caused by urban freight movements—the majority of which are by road. Road freight vehicles operating in an urban environment generally emit a greater proportion of certain pollutants per kilometer travelled than other motor vehicles, such as cars and motorcycles. This is due to their higher fuel consumption per unit of distance travelled and the fact that many of them use diesel as a fuel. However, when considered in terms of the quantity of goods carried, a well-loaded truck will produce fewer pollutants per ton or cubic meter of goods carried than say a van.

As well as making a journey within an urban area to collect or deliver goods or provide a service, a freight vehicle also has to be parked while loading, unloading or servicing activity is carried out by the driver away from the vehicle. This requires the parking of the vehicle either at the kerbside on-street, or in an off-street facility, either at the building being served or somewhere else sufficiently nearby. Many dense, central urban and residential facilities requiring goods or services comprise little off-street parking space, and in these locations freight vehicles compete for kerbside space with many other road users. Freight companies and their drivers are, therefore, subject to various challenges associated with stopping/parking their vehicles as well as the journey itself. These include:

- Parking and loading/unloading problems including complicated regulations concerning time and location, fines, lack of unloading space, and handling problems resulting from the kerbside design and paving material, for example, as well as the distance that goods may need to be carried or moved by hand in order to make a delivery.
- Customer/receiver-related problems—for example, identifying the exact address can be difficult and for some types of delivery there will be a need to obtain signatures as proof of delivery and perhaps the most common problem—narrow time windows during which receivers are willing to accept deliveries—which leads to complicated scheduling requirements.

As discussed above, while it is generally possible to agree that urban freight transport is an essential part of the economic and social well-being of a city, there is also agreement that further improvements are needed. Urban logistics also suffers from the impacts of the rise in traffic congestion, as this reduces the scope for efficient, reliable deliveries to be made. Logistics strategies and improved technology, especially related to information systems, has opened up possibilities for major gains in delivery efficiency. Yet much of this has been lost because of the rise in general congestion levels in cities and because of the inflexibility of other parts of the urban logistics systems—for example, the options to deliver outside peak times. Urban congestion and an inertia in decision-making by both the public and private sector actors has imposed constraints on further improvements.

The Complexity Challenge

Urban logistics exhibits a number of complexities including:

- Heterogeneous commodities, resulting in complicated freight flows and a variety of transport sectors;
- Overlapping regulatory regimes;
- The trend toward “logistics sprawl”;
- The range of organizations involved in decision-making processes.

These points are discussed in more detail below.

The very varied range of commodities being transported in the urban logistics system leads to complexity. Different products flow through different channels from supplier to end user and they are carried by different types of transport operator using a variety of vehicles (types and sizes). Some food products, for example, require strict adherence to specific temperature limits and will be carried in specialist refrigerated vehicles. In construction, there are also vehicles dedicated to a single type of freight movement—for example, cement mixers. Small packages and parcels may be delivered by van or by bicycle or when combined with postal services—on foot. All of this results in a very complicated pattern of vehicle movements where the main influencing factors vary between sectors.

Regulations applying to freight movements come from different sources. For example, emission standards in Europe have been established at a European Union wide level with increasingly stringent limits set on emissions by new engines for trucks. On the other hand, many regulations relating to urban logistics may be made and enforced by the city itself—for instance, there is no national standard for a low emission zone in the UK and certainly no Europe-wide standard, although there are broad similarities in some cases. At the street level then, there is considerable divergence in the way kerbside parking regulations and loading spaces are designed, operated and enforced. In some cases, such spaces will be controlled by a district within a city, leading to the situation where the rules at one end of a street could be different to the rules at the other end.

Increased urbanization has in turn resulted in generally higher values of land, especially in major urban centers. The rent or purchase price of such land has been too high to justify its use as distribution property. As a result, land classified for industrial and distribution activities has become increasingly scarce and much of this activity is now to be found only outside the city. Longer access

trips by vehicles delivering in the city may impose limitations on the type of vehicle being used—for example, it becomes less feasible to use a small electric powered vehicle if the city delivery trip is longer. City authorities have noted this development and some have now sought to create regulation to safeguard future land availability for urban freight use. For example, in the soon to be published new London Plan, the spatial development strategy for the city, the Mayor of London is proposing to include new and improved policies to retain, enhance, and provide additional capacity of logistics land, prioritizing these efforts in locations that are suitable for last-mile distribution services and support access to supply chains that extend beyond the city ([Mayor of London, 2019](#); [Transport for London, 2019](#)).

Different types of stakeholders can implement change and influence urban logistics in different ways. Public authorities may take the lead by changing regulations or by shaping policies in such a way as to contribute to broader urban sustainability goals ([Giuliano et al., 2013](#); [Holguin-Veras et al., 2020a,b](#)). In the private sector, two categories of stakeholders have received considerable attention: (i) freight transport companies or carriers and (ii) the receivers of products, for example, retail companies, offices and in some cases industrial companies. Most attention has probably been focused on the carriers, with many initiatives aimed at requiring or encouraging them to make their operations more sustainable, primarily from environmental initiatives. However, the scope for carriers to change transport operations may be limited because they frequently have to respond to their customers, who may be the senders or receivers of the goods.

Take as an example the scope to change the time of delivery in order to allow deliveries to take place outside the busiest hours on the road network (the peak hours). Many initiatives have been aimed at finding ways to encourage carriers to deliver in the off-peak hours ([Browne et al., 2014](#); [Department for Transport, 2011](#); [Holguin-Veras et al., 2011, 2014](#); [Transport for London, 2018a](#)). Despite many operational successes, carriers frequently encounter resistance from receivers, particularly from smaller stores and businesses where there are few employees and where the owner may already work long hours. Engaging with the decision-making stakeholders has been recognized as important and more attention is now focused on property owners and managers and business-led initiatives, such as Business Improvement Districts that represent local firms.

Urban Logistics Initiatives

A number of frameworks have been developed to categorize the many initiatives that can be seen in urban logistics. By comparing pilot tests, projects and initiatives around the world it has been possible for researchers to provide valuable insights for policy makers who are concerned with finding ways to improve urban logistics performance and sustainability in their cities. An extensive exercise to review urban logistics initiatives was carried out in 2015 with the leadership of Rensselaer Polytechnic University, in a project on behalf of the Transportation Research Board in the United States ([Holguin-Veras et al., 2015](#)). The project devised a classification system that allowed projects and initiatives to be grouped into seven categories divided between supply and demand initiatives.

Supply side initiatives include: (1) infrastructure management; (2) parking/loading areas management; (3) vehicle-related strategies; (4) traffic management. Demand side initiatives were categorized as: (5) incentives and taxation; (6) logistical management; (7) freight demand/land use management. The report was subsequently developed using further original research ([Holguin-Veras et al., 2020a,b](#)). The initiatives within these seven categories are discussed in more detail below.

Supply-Side Initiatives

1. *Infrastructure management*: The focus here is on changes to the built infrastructure—because most urban freight involves a road movement, then most of these initiatives are concerned with building new road infrastructure or making modifications to existing roads. Some of these can be considered as major—for example, a new road to bypass a congested area or one where there is high housing density. Others may be more minor, such as reengineering the kerb to allow deliveries to be made more efficiently or changing a ramp to enable loading and unloading to take place. In practice, minor changes to infrastructure can have important implications for freight efficiency.
2. *Parking/loading zone management*: Much attention in urban freight movement focuses on moving vehicles. However, in some sectors (e.g., package or parcel delivery), it is common for the vehicle to spend up to 60% of the time parked for unloading and delivery operations ([Allen et al., 2018a](#)). Therefore, ensuring that loading zones are managed efficiently can provide important benefits for carriers and, in turn, can improve the way the city center operates from a public authority perspective. Changing regulations about the time of access and the length of time that can be spent to load or unload has important efficiency impacts. In addition, designating areas for loading or unloading can be a major contributor to better urban freight operations.
3. *Vehicle-related initiatives*: As noted in the opening sections of the chapter, vehicle emissions have a major impact on urban air quality. As a result, a lot of attention has focused on improving existing fossil fuel emissions standards and also on the scope to change to alternatives such as electric vehicles. Furthermore, programs that have been designed to support off-peak hours delivery have also led to the search for standards relating to noise of both vehicles and handling equipment ([Sanchez-Díaz et al., 2017](#)). An important way to encourage a higher proportion of low emission vehicles is by creating low emission zones within which vehicles are only allowed to operate if they meet certain standards. Low emission zones—also known as clear zones or environmental zones—have been introduced by a range of cities, especially in Europe. One of the largest zones of this type is to be found in London which has also now introduced the ultra low emission zone ([Transport for London, 2020](#)). One issue for

transport operators has been that there can be argued to be some inconsistency in terms of regulations between cities in different countries. This can make for complications in some cross-border operations. Low emission zones may specifically restrict certain types of vehicle that do not meet specific standards.

1. *Traffic Management:* Vehicle access restrictions based on weight, size, or time of day are widespread initiatives taken by city regulators to limit what may be seen as negative environmental impacts from urban truck operations. Restrictions may make it more difficult for freight operators to combine deliveries and, in some cases, can lead to an increase in distance travelled or an increase in the number of vehicles (or both). A better understanding of urban logistics by public authorities has helped to reduce the unintended consequences of restrictions. Consultation with industry has resulted in changes to restrictions that have a positive impact—for example, reconsidering vehicle length limits may allow freight operators to continue to use the most efficient truck for the deliveries that are required.

Many cities have identified that some roads and parts of the network are not suitable for all freight vehicles. This may be because of the weight and size of the vehicle or in some cases it could be the products being carried (e.g., dangerous or hazardous cargo). In these cases, cities have defined specific routes for trucks to follow. Enforcement is an important issue when defining and maintaining such a route or network. Increasing interest now exists in the scope to use geo-fencing techniques to monitor and enforce such initiatives. Geo-fencing would require vehicles to be able to demonstrate their whereabouts in the network and the access to some parts of the network would be limited to certain trucks and types of operations.

Allocating road space can also be an important decision for public authorities. Initiatives such as “Complete Streets” in the United States have led to discussions about how freight vehicles should be accommodated in urban traffic plans (McCann and Rynne, 2010). Traditionally, vehicle weight and size limits have been widely used in cities to control vehicle movements in order to avoid large trucks being in sensitive and historic areas. However, restricting trucks according to size may result in the increased use of smaller vehicles which can have negative consequences for congestion. In the same way, access time restrictions may lead to more trucks being present in the shorter times that are available for delivery.

Demand-Side Initiatives

1. *Pricing, incentives, and taxation:* Road user charging or congestion pricing has been introduced in a number of cities around the world. In most cases, freight vehicles also pay these charges. However, research has highlighted that freight movements do not change much as a result of charges being introduced. This is mainly because carriers have limited power over the time of day of the delivery because that power lies with the receivers (or possibly the senders of the products). Incentives have been discussed as a means to encourage higher standards and better operating practices related to urban freight. However, there are relatively few examples of incentive schemes around the world. Certification projects whereby carriers can apply to receive a certification based on the quality and sustainability of their operations have been introduced with some measures of success—see, for example, the FORS scheme in the UK (FORS, 2018).
2. *Logistical management:* Managing urban logistics in new ways underpins many initiatives. These range from approaches such as urban consolidation centers and the use of lockers and collection points, as well as initiatives related to operations management, such as the routing of the vehicles and special training for urban freight drivers. The concept of consolidating products to achieve a reduction in the number of truck trips and distance run in urban areas has been promoted for many years. Consolidating products can improve the load utilization and ensure better loaded vehicle trips. However, it is sometimes argued that the consolidation operation adds time and costs to the activity. As a result, there has been commercial reluctance to adopt this approach unless there are strong regulatory or other reasons. Despite the reluctance many urban consolidation center schemes can be identified (Allen et al., 2012; Gonzalez-Feliu and Morana, 2010; Greening et al., 2015; Kin et al., 2015). The goal of using electric vehicles has also led to some support for the consolidation center approach. In many cases the lower range that can be accomplished by electric vehicles means that the operations are simpler when there is a consolidation center available at, or close to, the edge of the urban area.

Locker boxes, collection points, and other ways to support the rise in home delivery and e-commerce all have an important role in urban logistics (Morganti et al., 2014; Yuen et al., 2018). Delivery direct to the consumer can work very efficiently, but there are also many studies that have highlighted the problem of failed deliveries caused by the person receiving the products being absent at the time of delivery. Using parcel lockers or a collection point (such as a retail store) can enable a transport operator to make efficient deliveries and, at the same time, allow a consumer to receive the product at a time that is most convenient to them. As these systems become more widespread, the proximity of locker boxes and collection points to the home of urban residents has also increased, leading to greater satisfaction with such systems.

Finding the right size vehicle for urban freight operations can be challenging. Larger vehicles are required for the movement of bulky products or where there are many goods destined to one delivery point. However, for smaller packages and diverse loads, there may be scope to use smaller vehicles such as cargo cycles or light electrical vehicles. Other fuel sources may also be an option in the search for a lower environmental impact—for example, the use of biofuels. Cargo cycle use has increased significantly in recent years (Allen et al., 2018b; Rudolph and Gruber, 2017; Transport for London, 2018b) and such vehicles can now be seen providing package delivery and other services in many cities around the world. Despite the growth, the total scale of such operations remains modest at present, but there are signs of growth and such vehicles can be expected to represent a larger share of movements in inner city logistics in the future.

3. *Freight demand/land use management*: This can be considered as an important category in making fundamental changes to the way urban logistics is carried out. During recent years it has become apparent that many logistics activities are strongly connected to decisions about land use. As previously discussed, warehouse and distribution center activity that was formerly within city boundaries is often now found only on the edge of cities or even at some distance from the urban area. As a result, vehicles have longer access trips and the vehicle kilometers in relation to freight movements have increased.

The timing of deliveries can also be altered; changing to off-peak hours deliveries can have major impacts on the efficiency and sustainability of urban logistics, as well as reducing the freight vehicle contribution to emissions (Browne et al., 2014; Holguin-Veras et al., 2011, 2014; Sanchez-Díaz et al., 2017). Major gains have been achieved when such initiatives have been introduced in cities around the world. Changing the time of deliveries to move them outside the peak hours when traffic volumes are greatest has been shown to produce benefits (Browne et al., 2014; Department for Transport, 2011; Holguin-Veras et al., 2011, 2014). However, there has been resistance to implementing such initiatives, based on concerns about vehicle noise and disturbance to residents and also because the change could lead to additional costs for some organizations in the supply chain. Early discussions on this subject tended to lead to fears about delivery being made in the middle of the night. In practice, it is the scope to shift to a slightly later time in the evening or a slightly earlier time in the morning that seems to have had many benefits. When this change is combined with the opportunity to make what are called unattended deliveries, then the gains seem to be especially valued (Sanchez-Díaz et al., 2017). Unattended deliveries mean that there does not need to be a person present at the receiving address at the time the delivery takes place. Instead, drivers are either granted secure access to the delivery point or technologies that can ensure security in terms of delivery can be used.

A further important possibility is for receivers to find ways to group together or bundle their purchases and thereby reduce the number of vehicles required to make deliveries—such receiver-led consolidation approaches have received considerable attention (Allen et al., 2017; MacLean et al., 2019).

Mode choice is a very important topic in freight transport and logistics. However, in the case of urban logistics it has been difficult for companies to find viable alternatives to road deliveries using vans and trucks. Despite the problems, there are alternative modes used for urban deliveries and these include switching from road to the use of tram, rail or waterway. Over the past few years an increasing number of alternatives have become established in some cities. The scope to increase the use of modes such as waterways is especially attractive when considering the transport of bulky products such as construction materials and waste.

Discussion and Conclusions

In order to achieve successful implementation of the initiatives outlined above, a constructive process of engagement between the relevant public and private sector actors is required. This multistakeholder approach is necessary because there are many different actors involved in urban logistics and freight transport operations, and also because no single stakeholder is usually capable of solving the problem on its own. Urban logistics depends on decisions made by the public sector and by those in the private sector. However, the goals of organizations from the public and private sector differ and as a result it can be difficult to achieve a harmonious working relationship. Strategies for engagement include Freight Partnerships and Freight Networks (Lindholm and Browne, 2013; Quak et al., 2016).

As Holguin-Veras et al. (2020b) argue, public authorities typically lack detailed knowledge of how and why urban freight activities and operations take place—formal training is scarce and the level of information and data on urban freight movements is far lower than in the case of public transport and personal mobility. Almost all the operational and commercial decisions about urban freight and logistics are in the hands of the private sector, raising complicated questions about confidentiality and the scope to share data and insights. When addressing freight and logistics, urban public authorities have tended to rely on approaches based on regulation and traffic engineering.

This chapter has outlined the wide range of initiatives that can be implemented by public authorities to improve the performance of the urban freight and logistics system. However, as researchers have, there remains the need to (1) assess the effectiveness of initiatives and consider the advantages and disadvantages in different situations; (2) provide material that transportation professions can use to determine the efficacy of one initiative compared with another; and (3) identify the best ways to help public authorities take the necessary steps in improving urban freight and logistics in terms of management, policy, and planning (Holguin-Veras et al., 2020a,b).

Furthermore, the results of the research noted above also demonstrated that, in most cases, the initiatives discussed reduce congestion, either significantly or slightly, and initiatives in the group “Freight Demand/Land Use Management” were identified as having the most profound impacts. Moreover, those initiatives related to “Logistical Management” and “Freight Demand/Land Use Management” were not perceived to have significant negative effects. By contrast, some negative impacts were argued to exist for initiatives relating to financial approaches, as a result of increasing costs. Overall, the results of the work by Holguin-Veras et al. (2020a,b) show the great potential of initiatives in “Freight Demand Management” to reduce congestion with minimal negative impacts.

Research into urban logistics and freight transport has certainly grown significantly over the past 20 years. However, this is from a small base of researchers. At the end of the 1990s, there were already research conferences focused on urban freight and logistics, but the number of researchers attending was modest. Since then there has been a major increase in interest from cities and a parallel

growth in the number of researchers and the range of countries interested in this field (Browne et al., 2019). The research community has grown and the practitioners concerned with urban freight, and in particular those involved in the public sector and city authorities, have also increased. However, in comparison to practitioners and authorities involved in personal travel, the number remains very low. It is of considerable importance that the research that has been produced in the past 20 years is made more widely available to practitioners and policy makers and that guidance on implementation continues to be developed. If this can be achieved, then the promising progress outlined in this chapter will become far more widespread.

Omni-Channel Retailing and Omni-Channel Logistics

Omni-channel *retailing* refers to a business model that increases the customer experience by allowing the use of a variety of channels in a customer's shopping journey (Fig. 1). The increase in usage of digital technologies, social media and mobile devices has dramatically changed the shopping behavior of the customer and hence, the retail environment. This change necessitates retailers to rethink their marketing, supply chain, and logistics strategies. The customer journey not only involves the physical store, but also alternative sources of information (e.g., via mobile phones, internet, etc.), and potentially, buying online. In the marketing literature (Gallino and Moreno, 2014), this is referred to as the *ROPO* effect (Research online, purchase offline) versus show rooming (researching in a physical store and buying online [Gensler et al., 2017]).

Many initiatives aim to revitalize the offline retailers. Clearly, these retailers face challenges to compete with online retail, and are more and more in need of combining the traditional, offline channels with the growing (in size and importance to customers) online channels.

Omni-channel retailing thus involves the organization and integration of the different multiple sales channels (think of stores, website, etc.), mainly within the B2C (business-to-consumer) context. The customer is always central in this respect regardless of the actual *marketing* channel used. From a customer perspective, his or her demand is thus fulfilled seamlessly across all the channels. The customer experiences the brand rather than channels, hence omni-channel marketing. In summary, omni-channel marketing involves integrating multiple sales channels into a single-integrated sales channel, planned and controlled accordingly. Clearly, this buying process approach is a marketing oriented focus.

Figure 1 The shopping journey.

Obviously, there is a clear difference between the buying process of the customer and the order-fulfillment process, after buying. In the latter, delivery reliability and logistics costs are important drivers, also affecting the performance and experience of the sales process and the ability to sell. Specifically, the consumer not only asks for detailed product information, but also wants information about (real-time) availability, accurate delivery times, and a broad range of return options during the buying process. These decision and organization problems are typically in the omni-channel *logistics*' domain (Savelsbergh and Woensel, 2016).

Omni-Channel Logistics: Toward a Definition

We define omni-channel logistics as *all necessary activities involved with the functioning of the supply chain considering an omni-channel retail strategy* (Van Woensel and Broft, 2016). In its essence (Simchi-Levi et al., 2019), logistics and supply chain management aims at providing good service (the right product, at the right time, and at the right place), for a low cost. This becomes more and more complex in this omni-channel context, considering different channels to connect to the customers. In our definition, omni-channel logistics is mainly involved with the fulfillment process of the orders, in connection to these customers. More narrow, *e-fulfillment* deals with the fulfillment activities for online buying.

Fig. 2 gives an overview of the omni-channel logistics activities related to the supply chain. We simplified the supply chain in the sequence sourcing–production–distribution–retail/detail/e-tail–Consumer. Contrary to the most graphical depiction, the consumer is not the last element in this sequence, but more and more connects directly to all echelons. Think of the following examples. Consumers dictate that producers (e.g., fast moving consumer goods or fashion companies) to source their raw products in a clean, sustainable, and ethical way. Production is increasingly being done in a *batch-size-equal-to-one* way: NIKEiD allows customers to design and personalize their own Nike merchandise, being produced and shipped directly to their customers. Similarly, customers expect full visibility of the inventory in warehouses and can order their products directly from these sites, rather than going to the stores (e.g., DIY chains). Finally, the customer is also more and more in the lead on how and where their orders need to be delivered (the “logsumer” takes an active role on time, price, quality, and sustainability in decisions of logistics services [DHL, 2013]).

As in any supply chain, physical products move back and forth, next to information, and money flows. Adequately managing these flows is a key driver for successful omni-channel logistics. Over the past years, managing the reverse logistics flows became an important distinguishing success factor. Clearly, reverse logistics also offers a wide range of different possible return channels (aligned with the Retail, Detail, and E-tail channels).

Figure 2 Omni-channel logistics.

We summarize the different channels for reaching customers into the following three broad categories:

- **Retail:** The retail channel is primarily focusing on larger retail chains. Here, we see large to mega-stores with a large and broad assortment (not necessarily deep or specialized). These chains typically have large buying power and operate their own network of warehouses and, in many cases, their own vehicle fleet.
- **Detail:** The detail channel is more oriented toward smaller stores and shops (“mom and pop stores”). The assortment is smaller, but more deep. More experienced and specialized personnel work in the store. As they are usually not part of a larger chain, they rely on wholesalers. Sometimes, these detail stores are part of a large retail chain, for example, think of a city-center convenience store (express stores), offering a fast-moving assortment.
- **E-tail:** Consumer online orders in web stores are the primary focus of the E-tail channel. We see that many E-tail stores are part of a retail or detail chain. Pure online players are getting more and more rare, as the need for a physical network is increasing, due to the higher demand of the customers (e.g., same hour delivery).

As an example of the above categories think of flowers. Usually, in a retail setting, only few flower cultivars are sold (typically as ready-made bouquets). However, in a detail store, the assortment is much larger, also more variety in bouquets is available. In the e-tail setting, again, the same broadness might be reached.

Note that the e-tail channel penetrates throughout the complete supply chain and potentially affects the sourcing, production, etc. This makes it possible for manufacturers to reach out directly toward their customers, rather than via retailers, wholesalers, etc. Shortening the supply chain toward the customer can be very beneficial in terms of costs and in terms of short delivery lead times. On the other hand, the other channels still need to be handled as well. This again calls for efficient and effective omni-channel logistics.

Clearly, the retail and detail channels are typically bricks-and-mortar stores where customers need to go physically and buy their product. This is denoted in [Fig. 2](#) as *C2P*, short for customer-to-product. The e-tail channel is of course part of the online stores, web shops, in-store ordering with home delivery, etc. This is denoted in [Fig. 2](#) as *P2C*, short for product-to-customer. For both settings, the order fulfillment processes can be very different. Considering the omni-channel environment creates additional challenges, as we need to manage a more complex demand portfolio and multiple inventories with cross-replenishment over channels. All should be planned and controlled with total visibility of the supply chain, implying that integrated business planning is a prerequisite.

Over the past years, the role of sales platforms is increasing. Platforms like Amazon, Alibaba, Ebay, or Bol.com are growing in importance. Platforms originally were carrying and owning the inventory themselves. However, these platforms are moving toward a partner model setup, connecting multiple retailers. As such, the platform is not carrying inventory anymore, but only acts as the sales channel. The inventory holding is executed by the participating retail partners. In some cases, the participating retailers are making use of the logistics infrastructure of the platform (e.g., delivery, invoicing, etc.).

The latter system of organizing platforms is also observed to move toward a dropshipping execution model. Here, the retailer does not carry inventory, but uses the wholesaler to fulfill their customer’s order. The latter ships directly to the customer and the retailer earns the profit based on the difference between the wholesale price and the customer sales price. Similarly, within the omni-channel context, end-consumer orders are directly fulfilled from the various upstream suppliers ([Peinkofer et al., 2019](#)). The platform then serves as a collection of small to large retailers, as such broadening and deepening the assortment offered by that platform.

Decision Problems

In order to create a seamless customer experience, coordination between all logistics processes is crucial ([Hubner et al., 2015](#)). To enable demand fulfillment from anywhere to anywhere, decisions on network design, inventory management, warehousing, and transportation need to be aligned with the fulfillment options and promised lead times. In network design, it is important to consider that as well as pursuing economies of scale and cost benefits, a local presence is required. Without local presence, it is either unfeasible or too expensive to be able to offer the required short lead times to customers. In addition, real-time inventory visibility across all locations is required such that fulfillment options can be offered in real-time. The warehouse management systems and transportation systems need to be designed in such a way that picking, packing, and transport are feasible within the promised lead time to the customer.

Network Design

Network design is a typical supply chain process of strategic planning directly impacting its performance. Network design decisions are greatly affected by the channel strategy chosen. Omni-channel network design needs to consider more key performance indicators (KPIs) than the traditional network design methodologies.

Network design is about the physical configuration of the supply chain ([Ballou, 2001](#)). As such, network design involves organizing the supply chain network extending from raw material sources to the final consumption destination. Think of determining the number, size, and location of terminals, ports, plants, warehouses, stores, lockers, cross docks, etc. Specifically, it deals with how the network is as depicted in a very abstract manner in [Fig. 2](#), needs to look like^a.

^a As a side-note, note that network design is usually a redesign exercise, that is, improving the existing current network.

Traditionally, we evaluate the performance of the network along with two dimensions: customer needs versus logistics costs (Chopra, 2003). Various KPIs can be considered for both dimensions: response time, product variety, product availability, customer experience, order visibility, and returnability (customer needs) and inventory, facility, and (inbound and outbound) transportation costs (logistics costs).

Challenges

An adequate omni-channel network design requires considerations of the two dimensions presented above. However, since this omni-channel network fulfills both online and offline customer orders from anywhere in the network, an additional complexity arises. Moreover, since the customer connects to more echelons in the supply chain (Fig. 2), the proximity to the customer gains in importance, in terms of response time, and costs. Clearly, the integrated network design for an omni-channel strategy leads to high complexity and important challenges.

Clearly, C2P and P2C processes are difficult to separate, necessitating a network design that is able to handle both processes. Network integration to fulfill customer orders from all retail, detail, and e-tail channels is a key for successful omni-channel order fulfillment. Combining this integration with the increasing need for speed, calls for high-performance, and more dense networks.

Infrastructure and transportation costs need to be optimized by integrating the networks and adequately sharing the usage of warehouses and trucks. (Hubner et al., 2015) listed a number of order fulfillment networks, that is, either from the stores, from a warehouse, or directly from the manufacturer. These authors identified three large archetypes of networks for omni-channel logistic: (1) a fully integrated network (online and offline are organized from the same location), (2) a parallel network (online and offline are separately organized), and (3) a sequential network (online is replenished via the offline warehouse). These networks are however too limited, as due to the short response times, e-fulfillment centers need to be much closer to customers. Hence, fulfillment options directly from the offline stores are needed as well, creating one extra layer of complexity in the network organization.

Warehousing

An omni-channel strategy forces retailers to organize their warehouses not only as a traditional distribution center but also manage the online sales from their web-shops. Summarizing, two types of order flows are then received: (1) retail and detail store orders (large size, less frequent) versus (2) e-tail orders (small size, but highly frequent and irregular). This evolution toward more and irregular orders, and decreasing order sizes is a direct consequence of the omni-channel strategy (Hamberg and Verriet, 2012).

The material handling is the core activity in the warehouses. From a cost-perspective, this constitutes the largest part of the operational costs: "Most of the expense in a typical warehouse is in labor; most of that is in order-picking; and most of that is in travel" (Bartholdi and Hackman, 2017). Clearly, these processes that deal with the organization of the order flow and the storage and picking operations are most affected when implementing an omni-channel supply chain.

Challenges

The impact on the warehouse management and operations following an omni-channel strategy mainly impact the picking, sorting, and packing processes. A critical challenge is the ability to handle different transaction sizes within one warehouse setting, without losing efficiency in the key processes (Niels et al., 2006). Handling the different order flows (online and offline) puts pressure on the material handling flexibility. Picking of individual items versus pallet or case-pack picking is significantly different in terms of picking equipment, planning, and organization (i.e., real-time information availability and real-time communication requirements) for the warehouse management system (WMS), enterprise resource planning (ERP), and/or distributed order management (DOM) system.

Following the above discussion, separate material-handling systems seem to be required, as a fully integrated system, handling both online and offline flows, seems difficult. This could be either in two physically separate warehouses or in one building, controlled by independent systems. Moreover, in a B2C context with increasing online orders, picking quality is important. Advanced picking technologies (e.g., radio frequency terminals, wireless speech technology, and pick/put-to-light systems) are interesting design decisions, but their high investments require high order volumes for a viable business case. Next to the required high picking quality, online order picking involves small pick quantities for many items. In general, these activities are more labor-consuming than case-pack or pallet picking (Niels et al., 2006).

Adding the online order flow to the traditional flow gives rise to extra complexity in the warehouse operations. Outsourcing to a 3PL (third-party logistics) service partner is then an interesting solution. These 3PL service providers can leverage on their economies of scale.

Inventory Management

Customers expect high service levels, in terms of availability, delivery times, and reliability. On the other hand, operating the supply chain leads to costs, which needs to be kept under control. Inventory management helps to reduce these costs. Inventory models aim to balance the different cost factors (ordering, holding, shortage, salvage costs, and discount rates) in such a way that the supply chain performance is optimized.

Over time, inventory management has become increasingly complex in its effort to adequately consider, as much as possible, the underlying real-life situation. Although less representative of real-life, single-echelon inventory models are relatively easy to analyze.

More representative, but more complex, multi-echelon models are also available, depicting serial models, distribution systems and assembly systems (Ton, 2018).

Challenges

Putting the customer at the center of an omni-channel supply chain, leads to the expectation that the inventory should be available at any place (both physical and channel), at any time and in the right quantity. This leads to many more inventory locations in the supply chain. Another consequence is that inventory is more distributed in the supply chain, as such, losing the inventory pooling advantages, potentially leading to higher inventory costs.

Moreover, a careful characterization of out-of-stocks is needed within the omni-channel setting, as the product can be available in the company, but not available to the customer (e.g., wrong place or wrong time or dedicated to another channel). This last point also relates again strongly to the network design (e.g., proximity to the customer).

Many inventory models in the literature assume that consecutive orders cannot overtake each other (Nahmias and Olsen, 2015). This means that, once an order is allocated to inventory ("promised"), this inventory cannot be used anymore for later orders, but with an earlier due date than any previous order. For example, replenishment of the inventory happens on Wednesday, an online order comes in on Monday with a delivery due date on Friday, depleting the on-hand inventory. An order coming in on Tuesday with a due date on Wednesday cannot be fulfilled, as the inventory is promised for the Monday order, resulting in lost sales for the Tuesday order. Swapping or allowing order overtaking, would resolve this situation.

Advanced algorithms are needed, adjusting the retail inventory rules to better exploit these opportunities and order fulfillment challenges provided by an omni-channel strategy. Moreover, richer performance measures are needed. Product availability for a certain service level based on a single channel demand fulfillment strategy might not be sufficient anymore and does not cover all the discussed challenges in a sufficient way. Short-term seasonality effects on the demand and the connected inventory rules are needed as well (Ehrental et al., 2014).

Last-Mile Delivery

Last-mile delivery refers to the last transportation echelon in the supply chain. Traditionally, brick-and-mortar retailers are the last stock point, and the customer comes there (Quak and de Koster, 2009). As such, the last mile is toward the store. However, following an omni-channel strategy, click-and-mortar stores and their last-mile delivery toward the customer's home is exploding (Niels et al., 2006). Whereas the brick-and-mortar option gives rise to consolidated flows from warehouses to the store, the click-and-mortar sales leads to a magnitude of fragmented delivery locations with small drop sizes.

Note that the last-mile delivery is highly related to other discussed processes in the supply chain. To a large extent, the network structure and the availability of inventory determine the delivery origin and destination. As this last-mile distribution happens mostly in a city context, all relevant considerations and challenges originating from city logistics are highly relevant to mention here as well (Bektas et al., 2017).

Challenges

Several important factors for store distribution (the C2P situation) are discussed in (Quak and de Koster, 2009). Specifically, these authors mention three large categories, that is, urban policies, logistical concepts, and retailer-specific characteristics. Each influences the retail store delivery process and its performance. Following the evolution of larger assortments (i.e., high product mix), brick-and-mortar retailers are moving into more pull versus push supply chains. This leads to more fluctuating demand and requires faster and more frequent delivery toward the stores.

Also note that time-window policy and vehicle restrictions, as imposed by the urban policy makers, also create additional challenges for the performance of the last-mile delivery to stores. These policy measures lead to under-utilization of vehicles and more vehicles in the routing and scheduling operations (Quak and de Koster, 2009). Ghilas et al. (2016) aim to improve this drop in efficiency in searching for good combinations of people and freight within a *cargo hitching* context.

Clearly, the rise of the online channel (click-and-mortar), has given broader and deeper assortments to the customer, but also increased the pressure on last-mile delivery, following this e-commerce boom. In this case, the products go to the customers (P2C). Savelsbergh and Woensel (2016) discuss various opportunities to reach the customers in their preferred locations (trunk delivery, drones, etc.). Dabia et al. (2017) discuss a variant of the pollution-routing problem where, next to the cost parameters, sustainability in terms of greenhouse gas emissions are also considered (Tolga Bektas and Laporte, 2011).

Several new initiatives are observed in practice: crowd shipping (Le et al., 2019), urban consolidation centers (Dellaert et al., 2019), integrated routing and inventory (Song et al., 2019), horizontal collaboration (Hezarkhani et al., 2019), etc.

Return Logistics

Reverse logistics refers to the product flow going back into the supply chain, rather than out of the supply chain in the direction of the customer (i.e., forward distribution) (Fleischmann et al., 1997). Serving the customer from everywhere means that for product returns, the customer should have more options than merely bringing the product back to the store. These options range from physical store returns, parcel shops, locker walls or being picked-up at home. Return requests also happen via a wide range of possibilities: internet, mail, phone, social media, etc.

Table 1 Buy and return options

<i>Return</i>	<i>Buy offline</i>	<i>Buy online</i>
Collection point	(1)	(2)
Home pickup	(3)	(4)

Challenges

Providing a generous return policy reduces the customer's reluctance to buy online and creates confidence. Moreover, it has positive effects on sales volumes and revenue. On the other hand, this increases overhead costs and complexity in the return process (Mukhopadhyay and Setoputro, 2004).

Combining the forward and return flows gives four possible combinations (Table 1). Each combination in Table 1 already gives rise to additional complexity in the supply chain. However, within an omni-channel strategy, *all* combinations would ideally be offered to give full flexibility to the customers. Combination (1) is the most standard one, existing for a long time within a brick-and-mortar setting. The other combinations (2), (3), and (4) exist following the growth of the online market. The collection point returns for combinations (1) and (2) lead to extra movements of the customer. In this case, retailers aim to use their physical network (e.g., stores) or the network of a service provider (post office, collection points) as effectively as possible. Home pickup of the returns is an expensive solution, but the least effort for the customer. Adequate routing and scheduling, combining pickup and delivery along the same routes, are much needed here (Peng et al., 2018).

Closing Remarks

An overview is presented of a selection of important logistics challenges in adopting an omni-channel strategy. This retail strategy leads to new models and insights which might not be there to the full extent. Especially, this integration of offline and online sales channels has many implications for current logistics and operations models. We hope that this chapter delivers some insight into these challenges and implications.

Introduction

Disasters, conflicts, crises, and pandemics have one thing in common: they impact on livelihoods and require that people assist one another. It is the discipline of humanitarian logistics that has taken it on itself to focus on the delivery of aid to people in need. Humanitarian logistics has come a long way from a reactive, ad hoc way of collecting and delivering materials, to a coordinated, complex, global, and professional effort of delivering aid. Notwithstanding rapid developments, challenges in this area will always prevail, and come with the next natural hazard actually impacting on human lives, or the outbreak of the next conflict or next pandemic.

Given that the core of the discipline is to deliver aid, freight transportation is an essential part of the overall logistical effort. This goes so far that many humanitarian organizations regard logistics as synonymous with transportation (Kovács, 2018). This may be a narrow view, not just with respect to logistics, but also on the humanitarian supply chain. However, it illustrates the point about the importance of transportation in this area. What is more, humanitarian organizations have themselves been likened to logistics service providers, 3PLs, and 4PLs (Abidi et al., 2015; Jensen, 2012; Vega and Roussat, 2015). After all, they extremely rarely manufacture any of the goods they deliver, while they purchase, pre-position, prepackage, and deliver all sorts of materials and finished products for their teams and for other humanitarian organizations (Vega and Roussat, 2019). Many are specialized in some product groups that relate to the thematic clusters they operate in, such as food, shelter, health, water and sanitation, etc.

Overall, of course, the same logistical principles apply to humanitarian logistics just as well as to any other application area of logistics and transportation. Yet, humanitarian logistics does also have some special features and faces particular challenges. These will be in the limelight of this article.

Special Features of Humanitarian Transportation

The very aim of humanitarian logistics being to assist people in need makes it different from any other application area of logistics and transportation. There are at least two main issues that stand out from this aim:

- This being a not-for-profit environment; and
- That it is needs-driven.

Humanitarian logistics has these features in common with emergency services or public health and, in fact, many of the logistical models and solutions developed for those areas are easily adaptable to the humanitarian context. Other models and solutions require more adaptation, as one cannot just not deliver to areas or groups of people that would not result in profit, thereby cutting off remote areas, difficult-to-navigate informal settlements, or dangerous environments, as often it is exactly in these spots where people are found who are most in need. To some extent, the problem is not just one of access to people in need, who may even be behind dynamically morphing lines of conflict, but also to identify and find people in need who may be actively hiding or are constantly moving, either due to a conflict, their position in society, or a stigma related to their health condition. The very aspect of mobility of vehicles used in freight transportation can be used to address this problem, converting trucks to distribution points or even donkeys to mobile clinics, or vessels to warehouses or hospitals (Tatham et al., 2016). In other areas of humanitarian logistics, containers have been used to set up different types of facilities, whether warehouses (Şahin et al., 2014), offices, or actual shelter.

At the same time, being needs-driven is quite different to responding to the indefinite nuances of demand. Again, it is from healthcare or emergency services that one can apply the concept of triage, in that cases are addressed in terms of their degree of urgency. There are some quite advanced models that have been developed to assess the needs of a population, and to further also assess the vulnerabilities versus capacities of individuals to determine who is in greatest need. Minimum standards of a response have also been set in the SPHERE standards, which outline details from the liters of water per person per day, to the square meters of shelter per household to the maximum weight of package sizes so they can be carried by individuals in the absence of any equipment. Apart from that, however, opinions vary as to the service level that meets needs, and whether the aim is to restore what people had, or to build back better, or to contribute to individual and community resilience. The target is constantly shifting.

The Context Impacts on Modal Choice

Other special features of humanitarian logistics stem from the impact of the actual “event” a so-called humanitarian program is responding to. Natural hazards and conflicts tend to impact greatly on the infrastructure around them, including on the transport and energy infrastructure. Destabilized, if not destroyed, ports and airports also impact on what is left in terms of modal choice, or at least vehicle selection. Railway lines often need to be rehabilitated and many roads may be unpassable, and bridges down, or are only capable of operating with limited capacity. Countless optimization models have been developed for vehicle routing in disasters, facing the common problem of not knowing which routes are *de facto* still available, and for which types of vehicles. Aerial photography (whether from satellites or drones) can help, but is not yet there to establish not just that a bridge is still standing, but that it can take a particular axle load.

Modal choice is not only restricted, however. Humanitarian transportation has come up with fascinating solutions, from the use of “quake jumpers” (i.e., people who jumped out of helicopters to assess the needs of populations trapped in the mountains of Kashmir after an earthquake) to riverboats in the Congo, dhows from Djibouti to Yemen, and all kinds of pack animals. Rare to be found in the typical logistics textbook, it is quite useful to know, for the humanitarian logistician, which kinds of loads different pack animals can take, for how long, and with what speed. As a side note, who would have known that lowland mules could have vertigo and refuse to ascend a mountain trail?

Perhaps the most misleading yet dominant picture of disaster relief is that of airdrops. Far from ideal, these are in fact applied as last resort. After all, without people who can oversee the distribution of aid in the last mile, it is the strongest and fittest, rather than the people in the most dire need, who are reached with such deliveries. Yet, air cargo is essential and much used in humanitarian transportation, especially in the very first moments of disaster relief. Sadly, while other transportation modes could at times be faster (Tatham et al., 2016), it is the image of air cargo being faster than any other mode of delivery that has led to the persistence of air cargo as the preferred mode of transportation in inbound logistics. This is despite the fact that air cargoes are more likely to get stuck in customs—leading of course to higher overall lead times after all.

When it comes to larger volumes and steady flows on the inbound, it is the combination of sea and road transportation that comes to the rescue. Banomyong and Grant (2016) have developed a humanitarian aid transport reference model that revisits all these constraints and requirements along a time line after a disaster. The guiding questions of the humanitarian aid transport reference model are as follows:

- What are the needs and requirements of the affected area?
- Can aid be diverted by land or sea within 24 h?
- Can it be diverted or bought locally after 24 h?
- Is the affected country landlocked?

As the last of these points indicates, responding to disasters in landlocked countries comes with further challenges. The disaster region may have its own views on treating incoming cargo for disaster relief, but they are not always shared across transport corridors when it comes to transit transport (Beresford and Pettit, 2019), as exemplified also in Choi et al. (2010) and Beresford et al. (2016). At the same time, movement can be restricted back out from the disaster area, either out of the fear of displaced people crossing the border as refugees, or for wanting to restrict the spread of pandemics.

You Never Walk Alone

Disaster relief is not a one-man show. It requires the combined effort of many organizations. Thus, many endeavors have focused on the coordination of aid deliveries, whether in the form of regular meetings to keep one another informed, to more actively establishing who delivers what where and in which time frame. Structured approaches to such coordination include alliances (e.g., the UNGM platform shared across UN agencies, the IASC Consolidated Appeal Process, and the ACT Alliance for Protestant and Orthodox organizations) to more those with an explicit logistical focus, for example, the Logistics Cluster, the Fleet Forum, the Logistics Emergency Teams, or the Humanitarian Logistics Association. Of these, the Logistics Cluster has both a global and a very operational disaster-specific coordination role in case of large-scale disasters (with a UN presence). Both they and the Fleet Forum also set standards, develop templates, and are used to exchange experiences. The latter is at the very heart of the Humanitarian Logistics Association, which has a strong focus on the professionalization of the discipline.

There is also a considerable commercial interest in the humanitarian sector. Apart from the sheer magnitude of this “industry” (OCHA’s Global Humanitarian Overview 2018 indicates 135.3 million people in need, 97.9 million people to receive aid, and the requirements of 25.2 billion USD to be able to deliver this aid), the reasons for companies and especially logistics service providers to get involved are many (Bealt et al., 2016; Tomasini, 2011; Vega and Roussat, 2015): apart from the very commercial interest in this sector, this involvement is used as a corporate social responsibility initiative, to attract and retain a motivated workforce, to the commercial reason of helping a disaster area to get back to business (i.e., the LSP’s core business) sooner, to using this as a market entry to a particular region, and to wanting to learn from the agility of humanitarian organizations. However, the interests of humanitarian organizations and LSPs do not always align, especially not when an LSP is required to be involved (rather than wanting to be), or when it comes to the *modus operandi* (Bealt et al., 2016; Falagara Sigala and Wakolbinger, 2019).

The Humanitarian Transportation Chain

Broadly speaking, there are three main ways in which a humanitarian delivery can take place:

- With the same humanitarian organization handling everything from procurement to delivery in the last mile;
- Through a myriad of organizations and implementing partners; and
- Through convoys.

The first option signifies organizations that value their neutrality and independence even from other humanitarian organizations, but also the newbies that have not yet heard of all the existing coordination platforms. As for the professional ones, they tend to work in conflict zones and derive their legitimacy from working alone. Only in rare cases would they turn to the help of other humanitarian organizations, though they may in fact share some logistical information (stock levels, scheduled arrivals, etc.) through coordination mechanisms. That said, even these may engage commercial logistics service providers especially for inbound flows: with the main restriction to that being the lack of geographical reach of such LSPs in conflict zones.

The second most common option is that of a larger international humanitarian organization orchestrating the delivery of aid to a specific destination and people of concern. This is what is meant by humanitarian organizations, not to speak of their coordination platforms, acting as 4PLs (Abidi et al., 2015; Jensen, 2012; Vega and Roussat, 2015, 2019). In this vein, humanitarian organizations procure items for persons of concern and see to it that these items reach those people. In the extreme, this could not require any material flow through this focal humanitarian organization, as procured items can be delivered directly to their downstream implementing partners, with everything else being outsourced. Few humanitarian organizations have their own fleet for freight; what is covered under “fleet management” also in the Fleet Forum refers mostly to the 4×4 s humanitarians use for their own access to particular locations. That said, the management of this fleet has developed into an art of itself, with highly interesting solutions being used for the leasing and maintenance of the global fleet of international humanitarian organizations (Kunz and van Wassenhove, 2019).

Most likely, however, the focal organization will still be the consignee of the shipment in the country of operation, and then involve several LSPs and (humanitarian) implementing partners in the last mile. What is more, many countries require their own freight forwarders to be used within their territories, leading to cross-docking at the border from one truck to another (Kachali et al., 2017). On the other hand, the focal humanitarian organization can very well also be involved in the value-adding logistics activities: in the storage of blank goods till their destination is known, in their packaging, labeling, kitting, customization and assembly (Vega and Roussat, 2019), and in consolidating the transportation of different shipments (Vaillancourt, 2016) or, alternatively, outsource some of these activities to LSPs (Falagara Sigala and Wakolbinger, 2019). At the same time, specialized humanitarian activities may also be carried out, including (re-)construction, repair and maintenance, assembly of water and sanitation infrastructure, etc. (Vega and Roussat, 2019). To add to this complexity, humanitarian organizations also offer both asset-based and network-based logistical services to one another (Heaslip et al., 2018). Not surprisingly, notwithstanding the illusion that items are tracked to their final use, commodity tracking systems focus on the delivery of a shipment to the next implementing partner only. Instead, whether they have or have not reached their target population is assessed by independent consultants visiting this population when carrying out monitoring and evaluation surveys.

The third option of using convoys is again a last resort. It is mostly used in conflict situations where safe passage needs to be negotiated through particular transport corridors (Choi et al., 2010; Kachali et al., 2017; Tatham and Kovács, 2017). Convoys may still include the leasing of trucks for the specific operation, but are closely supervised and operated by humanitarian organizations themselves. They can be operated by one single organization (especially if that is the only one that has been granted access through a line of conflict) or involve the consolidation of cargo across several organizations.

New Developments in Humanitarian Transportation

Ever since its beginnings, logistics has constantly adapted to the evolution of the humanitarian context, responding to the different changes that the field has witnessed. After a pick on the number of natural disasters worldwide at the beginning of the 21st century, the following years have seen an increasing number of outbreaks of infectious diseases, conflicts and displacements, which have a

tremendous impact on the type of aid delivered. On the other hand, the global economic downturn has pushed humanitarian organizations to adopt a more cost-conscious approach (Heaslip et al., 2018), which in turn has an impact on how that aid is delivered. Finally, many humanitarian organizations have developed a particular expertise in certain areas, including the use of technologies, which substantially reshapes the humanitarian network and the relationships between humanitarian organizations and commercial actors. New developments have seen the light in response to these changes.

As the world moves toward more slow-onset disasters such as droughts, pandemics, and conflict-related crises, so does humanitarian aid. In these particular crises, which share the same characteristics as other disasters, humanitarian organizations have to deal with an extra layer of complexity, such as following “people on the move” even in the sea and sometimes finding people “hiding on the move” in the case of population displacement, ensuring cold chains for vaccines (which need to be maintained between 2°C and 8°C, or in the extreme case of the Ebola vaccine, require an ultra-cold chain of up to –60°C to –80°C) in places with no electricity, or following and developing safety regulations when responding to an infectious disease outbreak.

With the concern for cost reduction comes also the need to rethink the way humanitarian aid is provided. Cash-based assistance has come as a solution not only to shorten the supply chain, simplify procurement, and remove the need for many logistics activities, but also to empower beneficiaries by providing them with purchasing power that will be used locally and so contribute to strengthening the local economy. Thus, in addition to setting up and managing cash transfers instead of product delivery, humanitarian organizations move toward the localization of the response, mapping in-country capabilities and, when needed, building logistics capacity. This represents an important shift in the humanitarian logistician’s skill set: from being a jack-of-all-trades, to a logistics and cash office, but more important it shows the evolution that the context is having from product-based to more service-oriented.

Service provision across humanitarian organizations is a well-known fact. Whether it is simple logistical support from one organization to another, sharing services, or exchanging services, the many activities performed by international and local NGOs are at the heart of the servitization trend in humanitarian logistics (Heaslip et al., 2018). Many of the major and mid-size humanitarian organizations provide all kinds of logistics services to other organizations, but also to grassroots movements, health partners, public institutions, and governments, either ad hoc or as part of a larger agreement and both on a profit and not-for-profit basis. Also, these organizations engage in the sharing or exchange of logistics services (Vega and Roussat, 2019). One example of this is UNICEF managing procurement services during the Ebola crisis on behalf of 100 partners including GAVI, who in turn used UPS aircraft based in Cologne, Germany, to transport UNHCR and UNICEF equipment to the countries worst hit by the epidemic.

All these changes have, to some extent, been made possible by new technologies and their adoption for humanitarian relief. Information technology plays an important role in coordinating physical flows between the different actors of the humanitarian network. New technologies like blockchain and the Internet of Things help organizations to manage transfers and ensure security in the case of cash-based assistance, improve visibility through the tracking and tracing of goods, and in some situations support emergency response through enhanced geographical information and urgent deliveries by the use of drones (Tatham et al., 2018).

Conclusions

By and large, humanitarian logistics is of course just logistics in another context, whether considering strategic questions of transportation planning (Gralla and Goentzel, 2018) or operational ones of vehicle routing (Fikar et al., 2018). This context may though impact not only on the aim and outreach of a program, but in rather operational terms for any delivery, on:

- The members of the transportation chain, including the availability (or not) of logistics service providers, the intricacies of coordination and service tiering across humanitarian organizations, and the implementing partners distributing the aid in the last mile;
- Access to an area and/or to a particular group of people, including the routes and transportation modes that are still usable, and the way of gaining safe passage and the choice of delivery method; and
- Product-specific requirements of materials handling, for example, the requirement of medical personnel to handle health products; temperature control for various food and health items; and the requirement of being able to deliver cash and/or goods.

Yet, this context is constantly changing. Both new challenges and new solutions will emerge over time. Watch this space!

Biographies

Gyöngyi Kovács is the Erkkö Professor in Humanitarian Logistics, and the Head of Subject of Supply Chain Management and Social Responsibility at the Hanken School of Economics, Helsinki, Finland. She is also the co-editor-in-chief of the *Journal of Humanitarian Logistics and Supply Chain Management*. Her research interests include humanitarian logistics as well as sustainable supply chain management.

Diego Vega is Assistant Professor of Supply Chain Management and Social Responsibility at Hanken School of Economics, Finland, and Deputy Director of the Humanitarian Logistics and Supply Chain Research Institute (HUMLOG Institute). His interests include humanitarian logistics, logistics service providers, competence-based strategic management, and temporary organizations.

Introduction

Throughout the history of humanity, disasters, both natural and human-made, have hit the population and devastated infrastructure. In the last decades, the number and impact of disasters seem to be increasing, predominantly due to weather-related events, and trying to minimize their impact and consequences is an aspiration of Governments and organizations that involves many decision-making processes that can be optimized.

The word *Optimization* refers to the action of choosing “the best” (in some sense to be defined) among different options—what can be called “the feasible.” The Cambridge Dictionary states that optimization is the act of making something as good as possible. In the same way, it states that *logistics* is the careful organization of a complicated military, business, or other activity so that it happens in a successful and effective way. The terms *Military logistics* and *Business logistics* have a long tradition in operational research. In fact, logistics is an extension of something that armies throughout history have taken care of: the supply of goods, movement, and maintenance of armed forces. In a more general way, logistics can be defined as the process of planning and organizing to make sure that resources are in the places where they are needed, when they are needed, so that an activity happens effectively.

In recent decades, a new term has been coined: *Humanitarian logistics*. This kind of logistics is focused on alleviating the suffering of vulnerable people. In fact, humanitarian logistics has been defined in the Humanitarian Logistics Conference, 2004 (Fritz Institute), as the process of planning, implementing and controlling the efficient, cost-effective flow and storage of goods and materials, as well as related information, from the point of origin to the point of consumption for the purpose of meeting the end beneficiary’s requirements and alleviate the suffering of vulnerable people.

Humanitarian Logistics and Disaster Management

Humanitarian logistics can appear in different contexts, but it is in the management of disasters where its specificity is greater. Some definitions related to the field of disaster management (Ortuño et al., 2012) are next introduced.

- A hazard is a threatening event or probability of occurrence of a potentially damaging phenomenon within a given time period and area. It can be both natural and human-made.
 - Natural: naturally occurring physical phenomena caused either by rapid or slow onset events, which can be geophysical, hydrological, climatological, meteorological, or biological.
 - Technological or human-made: events caused by humans and which occur in (or close to) human settlements, such as complex emergencies/conflicts, famine, displaced populations, industrial accidents, catastrophic transport accidents, etc.
- Vulnerability: This is the degree to which people, property, resources, systems, and cultural, economic, environmental, and social activity are susceptible to harm, degradation, or destruction on being exposed to the consequences of a hazard.
- An emergency is a situation that poses an immediate risk to health, life, property, or environment.
- A disaster is the disruption of the normal functioning of a system or community, which causes a strong impact on people, structures and environment, and goes beyond the local capacity of response. It is a combination of hazard and vulnerability.
- A catastrophe is considered an extremely large-scale disaster.

Table 1 Differences between commercial and humanitarian logistics.

<i>Characteristics</i>	<i>Commercial logistics</i>	<i>Humanitarian logistics</i>
Objective pursued	Minimize the logistic cost (inventory and transportation costs, among others)	Alleviate suffering
Demand	Known or estimated	Unpredictable in terms of timing, geographic location, type and quantity
Decision makers	Few decision makers	Multiple decision makers sometimes difficult to identify
Periodicity	Usually repetitive	Sudden apparition of unexpected demand for large amounts
Initial resources	Controlled	Lacking
Transportation network	Stable and functional	Can be damaged Dynamically changing
Uncertainty	Mainly due to demand, price or resources	Additional uncertainty due to damaged structures, dependence on donations or safety concerns

From the beginning of history, disasters have struck human beings and they have had to face their impact and consequences. In addition, far from diminishing, disasters, natural or human-made, every year affect more people around the world. The use of optimization approaches to tackle disaster management problems dates back to the 1950s, where they were used to determine the optimal location of fire-fighting resources. In the 1970s the first models on emergency logistics were developed, facing some maritime disaster situations. The decision-making processes in disaster management are extremely difficult, due to the multiple actors which are involved and the complexity of the tasks addressed. Among those tasks, humanitarian logistics stands out as a field where optimization techniques can be of great help. From the 1980s up to now, a growing literature on the optimization of humanitarian logistics has been developed.

Note that based on its definition, humanitarian logistics also appears in contexts different from disaster management. However, it is in the latter where the application of humanitarian logistics is more complex and difficult and where more differences with commercial logistics appear.

Commercial Logistics Versus Humanitarian Logistics

Optimizing logistics processes has been at the core of operational research since the beginning. The business and commercial sector has contributed to the development of such methods and benefited from them, and the question about whether such methods can guide decision making in the humanitarian sector has interested both researchers and practitioners.

The main characteristics that differentiate humanitarian supply chains in the context of disaster management from commercial supply chains can be summarized in [Table 1](#).

These differences show the need for new optimization models that can be used in the humanitarian sector which address its peculiar characteristics.

The Disaster Management Cycle: Tasks and Decisions

In the decision-making processes needed in humanitarian logistics for disaster management, the context and the nature of the decisions to be made change over time, especially as we move from before to after the disaster event. Deciding about preventive actions to mitigate the effects of a possible future hurricane is not the same as deciding about the precise actions to undertake just after it strikes, or two weeks later. Time pressure varies substantially from one situation to the other, being at a maximum just after the disaster occurs, while uncertainty is greater when only hurricane forecasts are available. The same differences can be found in the nature of the decisions and the criteria considered by the involved actors. This has led to distinguishing four successive phases in the management of emergencies and disasters according to the main nature of the tasks to be performed and their temporal location with respect to the disaster event ([Altay and Green, 2006](#)), as illustrated in [Fig. 1](#).

The four phases may be defined as follows:

Mitigation: This phase encompasses the actions taken to either prevent the onset of a disaster or reduce the impact in case it occurs. Typical optimization models arising in this phase are the selection of infrastructures to reinforce, the location of permanent shelters or warehouses, or the allocation of resources for them, among others.

Preparedness: All the actions taken to prepare the community to respond when a disaster occurs. Typical optimization models arising are inventory prepositioning problems, location of temporary shelters and evacuation plans, among others.

Response: This phase includes the tasks and decisions taken just after the disaster strikes, and it is characterized by a short duration with high time pressure and high uncertainty. Typical optimization models arising are transport, evacuation, and distribution problems, among others.

Figure 1 Disaster management cycle.

Recovery: This refers to all long-term actions and decisions taken in order to stabilize and recuperate the normal functioning of the affected population. It is characterized by its long duration with low uncertainty and low time pressure. Typical optimization models refer to infrastructure recovery, among others.

These phases are not independent from each other, they could even overlap, and the process of disaster management has to be understood as a nonstop cycle (**Fig. 1**). In order to help in the decision-making processes arising in each of the interrelated previously mentioned phases, different optimization models can be developed, and in recent decades an explosion of literature regarding this topic has taken place. In particular, very good surveys on models and optimization techniques used in humanitarian logistics can be found in the literature.

Regarding transportation problems, they present different characteristics. Vehicles can transport people, goods or a combination of both. They can visit the same node more than once or not, and can traverse the same arc more than once or not. Subtours can be allowed or not. Problems can be multimodal (including different types of vehicles, trucks, helicopters, ambulances, etc.), multidepot (including multiple supply nodes and/or multiple vehicle initial locations), and multiloading (each vehicle can load multiple times, even in the same node). Models can split delivery or carry out transshipments in any node. Also, data can be static (single-period models) or dynamic (multi-period models), deterministic or stochastic.

We will focus next on two of the most important and complex transportation problems arising in the humanitarian context: evacuation problems (both in the preparedness and in the response phase) and last mile distribution problems (arising in the response phase), both aimed at saving the lives of vulnerable people and alleviating suffering.

Evacuation in Humanitarian Logistics

According to the United Nations Office for Disaster Risk Reduction, an evacuation “consists of moving people and assets temporarily to safer places, before, during or after the occurrence of a hazardous event in order to protect them. Moreover, evacuation plans refer to the arrangements established in advance to evacuate properly, as well as plans for return of evacuees and options to habilitate safe shelters in the affected area.”

Following the previous definition, evacuation problems appear mainly in the preparedness and response phases. In the context of the preparedness phase, it is necessary to design the evacuation plans, prelocate supplies and detect possible locations that will be used as temporary shelters. As part of the response plan, the actions to be taken in order to evacuate the affected population include the rescue and secure allocation of affected people and the distribution of basic needs. Sometimes the evacuation could be part of the recovery phase, following the reevaluation of the possible infrastructure failures that may occur during the response phase.

According to the [London Resilience Mass Evacuation Framework \(2018\)](#), the following forms of evacuation are possible:

- **Self-evacuation:** individuals will make their own arrangements to move from a place of danger or threat of danger to a safe place using existing public transport or their own mode of transportation. They require no assistance from the community beyond general warning and informing communications.
- **Assisted evacuation:** individuals are capable of transporting themselves but require some type of assistance, as indications regarding where to evacuate or by which means.
- **Supported evacuation:** individuals cannot evacuate by their own means and require support from the emergency services and public authorities.

In addition, evacuation problems may arise in buildings, cities, regions or collective means of transport, such as trains, ships or airplanes. Due to the increasing height of buildings and the expansion of travel, there is a large collection of works related with building, train, airplane, and ship evacuation.

In general, self-evacuation is encouraged, if circumstances allow. For this reason, self-evacuation has been vastly studied in the literature facing the problems of traffic congestion, bottlenecks, density waves, training lines, oscillations, patterns, and panic. These characteristics are traditionally modeled via nonlinear programming models and queuing theory. Besides that, in the field of Humanitarian logistics it is necessary to open research lines with methods related to supported evacuation. These include routing,

location and distribution problems. A characteristic to take into account concerning these models is data inaccuracy, since most censuses have information about where people live, but there is not accurate information about the population present in the area at the time an evacuation has to be carried out. Furthermore, dynamic models prevail over static models due to the variability of the characteristics, and the fact that uncertainty has to be captured via stochastic models. The usual constraints appearing in these models are flow constraints, to ensure proper movement of vehicles and people; capacity constraints in vehicles and shelters, and time-related constraints.

The primary objective of evacuation models is to maximize the number of evacuees, combined with minimizing response time or travel distance from the affected area to the safe one. Besides that, other objectives may arise, such as cost, coverage, reliability, security or equity, so evacuation models are in general multicriteria. The size and complexity of the resulting models imply, in many instances, the use of metaheuristic approaches.

Last Mile Distribution in Humanitarian Logistics

The distribution of humanitarian aid to the population affected by the occurrence of a disaster is one of the most important tasks to be carried out in the context of humanitarian logistics and disaster management. The Logistics Operational Guide of the Logistics Cluster states that “the distribution chain or channel represents the movement of a product or service from the point of purchase to the time it is handed over to the final user/consumer. Some of the distribution activities embrace materials handling, storage and warehousing, packaging, transportation, etc.” In particular, last mile distribution refers to the last leg of the distribution chain, dealing with the transportation of products or people from a certain hub or depot to their final recipient or destination. These definitions hold both for commercial and humanitarian logistics. However, if we focus on the latter, the products involved are usually humanitarian aid that must reach the regions in need. If, in addition, the situation is a disaster relief context, issues such as the lack of reliable information, the urgency to reach the affected people or the possible damages to the local infrastructure all serve to complicate significantly the decision process and the implementation of the distribution plans. According to these elements and other relevant information related to aid and vehicle availability, budget, demand, etc., the involved organizations need to define the target of the operation and the plans to be developed. Last mile distribution operations usually begin at hubs or regional warehouses and end at field warehouses, delivery points managed by other local organizations or even at the beneficiaries directly. The transportation of humanitarian aid may involve the use of heterogeneous fleets that could include, among others, vans (or minivans), trucks of different sizes, 4x4 vehicles, helicopters, etc. Their availability depends on the local resources and the characteristics of the existing infrastructure.

In last mile distribution there is a variety of elements to be considered when evaluating the performance of a certain distribution plan, or in other words, several attributes must be taken into account when deciding how the operations should be carried out. First, the cost of the operation is always a key issue in any real situation, no matter the circumstances, and the time required to perform the whole distribution is usually an important factor as well, not only to provide a good service to customers receiving purchased products but especially relevant when the recipients are affected people and there are lives at stake. However, in the context of disaster relief, there are additional performance indicators that arise naturally: for example, when the available aid is not sufficient to meet the requirements of all potential beneficiaries, it is crucial to ensure that the distribution is carried out in an equitable way, trying not to leave out certain population groups because they are difficult or expensive to reach (or for any other reasons). In addition, designing reliable and secure distribution itineraries, in order to avoid areas which may have been significantly damaged by the disaster or that could be dangerous due to likely assaults, is also desirable. All these elements should be taken into account jointly by the decision maker, when planning the operation, and yield multicriteria optimization models, as will be discussed later (Ferrer et al., 2018).

Most of the underlying optimization problems arising in last mile distribution are vehicle routing problems (VRPs), which can take many different forms: capacitated VRPs, pickup and delivery problems, VRPs with time windows, split delivery, heterogeneous fleets, loading conditions, precedence constraints... and even combinations of these or other variants with certain modifications. In some cases, the problem can be formulated as a single or multiple flow problem, which are usually easier to solve. Furthermore, most real problems have a dynamic (data change over time) and stochastic (there is uncertainty regarding certain elements of the problem) nature, which are important to consider but complicate the resulting mathematical models to a great extent. These problems usually have a combinatorial number of solutions, making them very hard to solve to optimality and requiring long computational times to obtain proven optimal solutions. For this reason, and also taking into account the urgency associated with disaster relief intervention, heuristics and other approximation methods are frequently used to be able to provide the decision maker with reasonable solutions within short running times. This is crucial, so that these models and methods can be useful in practice as decision making aids or tools.

Exact and Heuristic Methods in Humanitarian Logistics

In the humanitarian logistics literature, mixed integer linear and non-linear models have been developed and solved to optimality, but in real case applications some of them fail to give a solution in reasonable time, due to the complexity of the models. In the context of optimization, a heuristic is a method that solves a problem in a short time without guaranteeing to reach

the optimal solution. Heuristic algorithms are appropriate to complex optimization problems and/or problems that must be solved with high urgency. Both characteristics—complexity and urgency—are usually present in humanitarian logistics, especially in the response phase, so heuristics are frequently applied in this field. A metaheuristic is a special higher-level heuristic, which iteratively guides a subordinate procedure, mostly a heuristic as well, to find near-optimal solutions. Metaheuristics generally include learning strategies, in order to efficiently explore the feasible set and may incorporate mechanisms to avoid getting trapped in a local minimum.

Metaheuristics can be classified according to several criteria. One of these possible classifications deals with the way in which solutions are obtained. In the first group we can include metaheuristics in which the solutions are obtained by performing alterations to previously obtained solutions. Local search-based heuristics belong to this group. Local search algorithms start from an initial solution and iteratively replace the current solution by other solutions belonging to a neighborhood of the current solution. Some local search-based metaheuristics applied to humanitarian logistics problems are Iterated Local Search (vehicle routing), Tabu Search (vehicle routing, large scale distribution) or Variable Neighborhood Search (water distribution, infrastructure recovery). In evolutionary computation, that also fits into this first group, the solutions form populations in evolution. In each iteration, several modifications are applied to the solutions of the current population to generate solutions of the population of the next generation. Successful evolutionary computation algorithms applied to humanitarian logistics are Genetic algorithms (infrastructure modeling, inventory planning, vehicle routing, evacuation, etc.), but other evolutionary computation methods have been used as well (evacuation, last mile distribution, etc.).

The second group is formed by constructive-based metaheuristics. Constructive algorithms generate solutions by iteratively adding elements to an initially empty solution until a feasible solution is complete. Some learning techniques may be integrated to improve the construction of future solutions during the process. In some humanitarian logistics problems arising in an insecure environment, vehicles are forced to travel together forming convoys, so they can be escorted. In such problems, the strong links between the elements of the solutions make it difficult to apply metaheuristics of the first group, since any small alteration of a solution can make it infeasible. Instead, metaheuristics of this second group fit much better. Two of these metaheuristics that had been applied to humanitarian logistics are Greedy Randomized Adaptive Search Procedure (GRASP) and Ant Colony optimization.

Multicriteria Optimization for Humanitarian Logistics

An especially rapidly growing line of research in humanitarian logistics uses multicriteria optimization methods, which are necessary due to the multiple actors involved and the multiple objectives present in these types of operations. There are extensive reviews on multicriteria optimization in humanitarian logistics (Gutjahr and Nolz, 2015). Usually, criteria are classified in three categories: efficiency (i.e., cost), effectiveness (i.e., time, coverage, travel distance, reliability, and security) and equity (fairness), and these criteria appear in different combinations and with different priorities in predisaster and postdisaster models.

Some of these criteria have commonly been considered in the commercial logistics literature, but others are specifically concerned with humanitarian operations. In this way, poverty and armed conflicts increase security issues, and may affect not only the objectives, but also the very nature of the transportation models, forcing the vehicles to travel in convoys to increase security or the possibility of being escorted. The same applies to the equity criterion, especially important in the humanitarian field. It is usually modeled as fairness in distribution, allowing transport to reach far and costly demand points, or fairness in the delivery times.

Time and cost are the most common criteria in transportation models. Regarding time, papers propose the total waiting time, the sum of travel times, the sum of delivery times, or the maximal time of operation. Cost criterion usually aggregates fixed and variable costs. The coverage criterion refers to the total met demand, and finally, reliability is related to the probability that the network arcs will be available for transportation and with the probability of being able to follow the routing plan designed.

Regarding solution approaches to address multicriteria models, they have been classified in scalarization (aggregation of single objectives), Pareto optimization, goal programming, and compromise programming. When many different and conflicting criteria are present, the last two approaches are the most commonly used in humanitarian logistics. Goal programming gives a solution that satisfies the goals of decision makers, or if this is not possible, the closest solution to such goals, even if the solution is not always efficient. On the contrary, under some regularity conditions, compromise programming ensures that no other solution has better or equal values for all the criteria. Both methods are related through the mathematical concept of distance to a given reference point. Both can include weights for the criteria, to capture the importance given by the decision makers to each of them. When the importance of different criteria cannot be compared, as could be the case between saving human lives and cost of operation, it is possible to define priority levels and use lexicographical optimization to prevent any trade-offs between them.

Introduction

This article discusses the role that transport plays in the context of events and event logistics. In the 21st century, events dominate our cultural landscapes and inhabit the lives of people of all ages, backgrounds, religions, nationalities, and ethnicities. For the last 2 decades, the study of events has entered the academic curriculum, with researchers and practitioners developing a growing range of literature that instructs and analyses, questions and resolves, written by, for, and with those who deliver events, and, increasingly, those who wish to study events management, as the field professionalizes around the world.

What we now know as “events” bring people together in a specific place, for a specific period of time, to engage in experiences and activities. This meeting together is with a purpose. Such gatherings may comprise people that are known to each other, such as family or close friends, or they may bring strangers together who have never before encountered each other and who may never connect again. Events range from small, intimate affairs to complex global mega-events engaging with hundreds of thousands, or even millions of people in one place. A major component of events is the logistics of bringing those people together to one location, ensuring that all the resources needed for the event are present in a timely fashion, whether the event is held in a permanent purpose-built or adapted event venue or in one that has been temporarily created for the specific event. In observing the world around us, we can identify events that contain cultural meaning, events for business purposes, events with political and state functions, personal celebrations and rites of passage, leisure activities and entertainment, education, and sport (Bowdin et al., 2011; Getz, 2005; Raj et al., 2009).

Transport and event logistics are vital constituent parts of the event planning process, as shown in the model in Fig. 1.

In telling the story of the development of an event, there are multiple transport implications and impacts on the event logistics that are necessary to enable the event to proceed. Travel is a vital element, as events bring people together, and much of the planning process involves managing logistics, which inevitably includes transport, whilst pre-event logistical considerations also include organizational aspects such as site visits and enabling face-to-face communications through meetings for planning and coordinating with suppliers to outsource support services. Post-event activities include transport logistics through face-to-face debrief meetings and evaluation reporting.

A key element of event logistics that requires transport is the onsite delivery of goods and services to and from the chosen event venue: these will take place pre-event, during the event, and post-event. The range of deliveries will vary from one event to another, and the type of venue will influence the requirement for deliveries onto the site. There are many different types of venues, and, increasingly, there are “hybrid” venues that have a primary function that may or may not relate to events (Hassanien and Dale, 2011). The venue plays a key role in defining and creating the event experience. Financial pressures and concerns about making the most of a space, combined with the burgeoning requirement for events venues, have led many organizations to open their buildings and spaces up for hire for the purpose of hosting events, in return for a financial contribution to enable these organizations to survive. Whether operating on a commercial basis or not, event venues range from purpose-built convention centers, hotels, and sports stadia to fields, parks, and churches, and from historic houses to schools and universities. Meanwhile, many sports organizations responsible for managing football, cricket, or rugby grounds are keen to increase the financial contribution by hiring their facilities out for other non-sports events (John et al., 2013). All of these venues require access for deliveries, as well as access for people working at and attending

Figure 1 The event planning process (Dowson and Bassett, 2018, p. 24).

the event, before the event, during the event, and even after the event. However, many event creators choose to use greenfield sites for their event locations. This means that literally everything has to be brought onto the site, to enable the building of a temporary event venue, and returning the site to its original state afterward. The adage “leave no footprint” may be more popular with those who affirm sustainable values, but, whether it’s a festival, a weekly park run, or even an illegal rave, the carrying away of event detritus and removal of the physical resources needed to deliver the event require managed logistics.

Traffic Management

For event participants, arriving at the venue and leaving the venue are important contributors to the overall event experience, as the initial and final components, and all too often include enduring long queues for toilets, refreshments, and cloakrooms inside the venue, and queues for traffic when leaving the venue. The impact on the local community in the area surrounding the event should be taken into consideration, whether roads are signposted, closed completely, rerouted as one-way, or simply clogged up with slow-moving vehicles trying to enter the event car park or drop off attendees or supplies; meanwhile, local residents are unable to go about their daily lives. Event timing is an important factor, for example, combining an event start with the weekday evening rush hour is more likely to lead to traffic queues as tired commuters, anxious to get home, clash with excited event goers, eager to see their favorite band playing. Weekend traffic may have different peaks and troughs, or be equally busy, depending on the area, and so traffic management plans need to include local knowledge and experience of road conditions for travelers at all times. For example, in Yorkshire, United Kingdom, travelers hoping for a smooth journey to the English East Coast over the August Bank Holiday weekend are very likely to sit in traffic for hours as floods of young people make their way north of the city for the popular annual Leeds Festival, and have sympathy for parents dropping off and collecting their offspring and assorted friends, as they queue to get onto the site, crawl within the site boundaries to park, and then queue again to make their way out, a process that can take hours. In 2016, technical and production staff arriving to set up stages at the Glastonbury Festival spent up to 13 hours sitting in their cars and trucks queuing to get onto the site because some festival attendees had decided to arrive early, blocking the narrow country lanes with their parked vehicles when they were rightly denied early access by festival security staff.

The legal and regulatory requirements for managing transport elements of an event can be found in health and safety guides promoted by industry associations to develop good practice. For the topic of Transport Management, such advice is available in an online publication, “The Purple Guide,” which contains a specific chapter that addresses transport logistics onsite at events held in the United Kingdom (The Event Industries Forum, 2014). The chapter provides a useful health and safety resource for transport logistics at events, even in wider international contexts.

The Purple Guide details the following counsel:

- Once on an event site, the movement of site vehicles and traffic are found to be a major cause of serious and fatal accidents, so organizers are urged during the planning stages of the event to assess the risks of vehicle movement at all times, from pre-event setup and post-event breakdown, to imposing considerable restrictions on movements during the event, when the site is likely to be full of people.
- A traffic management plan is required as part of the event license, to control not only internal site traffic but also to consider the implications for external traffic and public highways leading to the event location and venue. Planning takes account of the requirement that pedestrians and vehicles should be segregated onsite at all times, which leads to fenced-off internal traffic routes within an outdoor festival site, for example, where possible, incorporating one-way systems and minimizing the need for reversing vehicles.
- Appropriate training and authorization processes are required for drivers and traffic marshals within the traffic management plans, with protocols in place and communicated to all.

Appropriate official signage should be used. In the United Kingdom, the Purple Guide advises that event organizers should agree detailed traffic sign plans and schedules with police and local authorities, and consider using a sign contractor for events where the majority of people will be arriving by cars or coaches ([The Event Industries Forum, 2014](#)). On-street signs should be placed and erected following guidelines in the Purple Guide, and by accredited personnel only.

In the United Kingdom, only the police can legally undertake traffic regulation on the public highway, although they may accredit some trained and approved stewards to work under their direction under the PATO (Police Accredited Traffic Officers) scheme. On a private event site, stewards can direct traffic. Logistical requirements will determine how many stewards will be required (directing traffic and managing closed or access-only roads), and all stewards should receive correct training and PPE (Personal Protective Equipment), such as high-viz clothing and appropriate weather protection.

The UK Construction Industry Research and Information Association (CIRIA) issued Guidance on Designing for Crowds in 2008 ([Rowe and Ancliffe, 2008](#)). This guidance considers the operational requirements of venues, and includes the following transport and logistics aspects: routes and way finding including signage, security (gates, search areas, CCTV, and communication), disabled users, deliveries, access for queuing and ticketing. The CIRIA Guidance is intended for designing venues for crowds but is useful for all aspects of venue design and encourages event organizers to engage all stakeholders actively in the design from the start of the planning process. Transportation and access considerations form a vital component of the guidance, which encourages event development teams to visit similar, existing environments and meet with operational staff to identify what works well and what does not work well in the venue and location. This information can be effectively used to develop the transport planning documentation, with special consideration for people with disabilities and impaired mobility, and for transporting goods and services onto the event site.

In a post-9/11 world, in which vehicles can be weaponized, events have been targeted by suicide bombers in terrorist acts. Two such attacks on events took place on November 13, 2015, in Paris, France, where the entrance to the Stade de France (football stadium) was struck by three suicide bombers during a football match, and a mass shooting took place during a concert by the Eagles of Death Metal in the Bataclan Theatre, killing 130 people and injuring another 413. On September 22, 2017, at the end of a concert by the singer Ariana Grande at the Manchester Arena in Manchester, England, a suicide bomber killed 22 people and injured 139. Post-Manchester there has been a focused response by the security services (including police) and event planners, taking on board the security and safety impacts in event logistics and planning, which impacts on transport arrangements for people and deliveries of goods to and from event venues. Following attacks in Nice, France, on July 14, 2016, when a truck was deliberately driven into crowds celebrating Bastille Day, governments and police forces have reviewed event safety measures. Security technologies, surveillance, and policies to guide best practice are readily available, along with experts to implement and advise ([Safe Events, 2019](#)).

Transporting People

A key component of event logistics involves the transport of people to and from the event location. The range of people involved in an event can be assessed through identification of the different stakeholders. Every event has multiple users who access the site, and different events and different sites will have different logistical requirements. These users might include the following groups:

- Clients
- Staff (e.g., technical staff, security, marshalls, cleaners, venue staff, caterers, event managers, event production staff, etc.)
- Performers and artists
- Promoters
- VIPs
- Event attendees
- Users with disabilities and mobility issues
- Emergency services

Each of these groupings of people has different logistical requirements, some of which are potentially in conflict with others. Staff working onsite at an event may be in-house or outsourced, but they will need access to the site prior to the event (sometimes for days, weeks, or even months), throughout the duration of the event, and after the event (again, sometimes for days or weeks, as the site is returned to its former state). This access may involve traveling in on a daily basis, or less frequently, perhaps from long distances, as well as traveling around the site itself. Staff will need to familiarize themselves with the site layout, and especially the back-of-house areas. For a festival site, this includes special access routes that are not open to event attendees, but which are specially required for deliveries, emergency vehicular access, transportation of event production resources, and waste removal (including emptying toilets). Event performers and some VIPs may need specialist access, with more direct routes than those available to event attendees. For example, the site may need to be accessed via helicopter, to avoid road congestion and ensure timely arrivals onsite. Access will be restricted onto and within the event site where groups and individuals will be identified onsite by their accreditation, usually in the form of passes, stickers, or wristbands, which may be timebound, as well as enabling or restricting access to specific zones, areas, or buildings/structures, defining back-of-house and front-of-house accessibility. Increasingly, such labeling identifies the named person allowed onsite, through the use of scanned barcodes or QR codes. Users of the site with disabilities and special requirements may need to access different routes within an event site, and music festivals will often have specially reserved camping areas available near to facilities and event activities. Wheelchair and other disabled access and mobility considerations are an important part of

event logistical planning, with expert advice best taken from those with specific experience of the requirements. The placement and size of blue badge parking sections for people with disabilities and mobility issues should reflect the numbers attending an event, but often assumptions are made rather than plans for known participants and event staff. Some festivals provide shuttle buses from accessible campsites to the event stage areas, and most include a free pass for a carer. Electric wheelchairs for use on an event site may require electric charging facilities to last through the whole event.

Types of Vehicles and Their Uses

Event transport can be provided by specialist companies, providing quality transportation in a range of vehicles, from cars, MPVs, mini coaches, and large coaches, with professional experienced drivers and chauffeurs with local knowledge. Such companies provide quality transportation to the events industry, whether for meetings, conferences, sports events, and festivals, supplying services such as ground support, liaison with event organizers and venues. Recognition of sustainability issues includes the development of carbon offset programs, and quality attention to detail.

Examples of transport use for events include:

- Transport from hotel to dinner venue for 200 conference delegates, using three coaches out and two coaches providing a shuttle service back, every 15 minutes, from 10.30 pm to midnight.
- Passenger transfers, with luggage distribution, for an international conference, with 12,000 transfers over 3 days: 750 conference delegates arriving from all over the world, staying in 12 different hotels in and around a city.
- Bespoke chauffeur-driven services, for airport transfers, client show rounds, local tours and transfers, long-distance meetings, corporate entertaining, ceremonies and dinners, using executive cars or people-carriers.
- For disabled or infirm event participants, providing assistance getting in and out of vehicles, escorting to and from buildings, with or without walking aids or folding wheelchairs accommodated within the vehicle. Specialist support for visually impaired passengers, with or without guide dogs. Transporting multiple guide dogs.
- Corporate and special event vehicles for national and international coach tours, sports teams, and music tours.

Transport Logistics Considerations in New Build Permanent Event Venues

Considering the transport logistics of a new build permanent event venue requires significant planning, with documentation developed in collaboration between multiple stakeholders, including local authorities, site owners, site management (if different), and specialist consultants, in a Design and Access Statement. This statement contributes to the supporting documentation submitted within the planning application process. New venues and their surrounding space are explicitly designed to promote a sense of arrival, enhancing attendees' expectations, whilst meeting requirements for access and egress for pedestrians and vehicles throughout normal operations and in emergencies. Pedestrianized space is prioritized, for people to gather as they wait to enter the building for a performance, and providing safe capacity for departing crowds.

New access roads and enhanced pedestrian footpaths and cycle routes may be needed to improve existing access to the site of a new venue. The aim is to minimize vehicular access and encourage event attendees to travel by public transport and on foot. Access to the site may be designed to enable deliveries and other vehicular access and departure with minimal disruption to the existing traffic flow. Environmental sustainability concerns and building on existing public transport links discourage event participants arriving by car, using existing car parks. Disabled parking is prioritized, with disabled parking bays adjacent to the venue, with additional disabled parking in nearby public car parks.

Significant attention is paid to enabling connectivity, including arrival routes by foot and bicycle, developing new access points, with well-lit footpaths and cycleways to promote the safety and security of pedestrians and cyclists in the area. Environmental sustainability considerations closely combine with social and economic concerns to improve surrounding areas.

On Tour Perspectives

Touring events are common, as musicians, sports teams, and even conferences travel nationally and internationally, performing, playing, or delivering their messages. The logistical structure of a tour can be complex and is subject to multiple factors (which sometimes appear illogical to the observer). The road show is a convenient method of engaging with multiple audiences in different geographic areas, especially in the era of experimental marketing and product activation events. The events team managing such a road show might also be involved in the delivery of other events, as well as coordinating suppliers, from audiovisual technical support to trained facilitators and industry specialist speakers, which may be consistent, or vary from one event to another, as the event moves around the country to the next location and venue. Delivering two, 36-hour business events a week, should be easy enough, with travel within the weekday period being as limited as possible. However, other factors may conspire to force contiguous events to be held geographically further apart than seems logical, such as the availability of suitable (and appropriately priced) venues that meet diverse needs of participants and organizers.

In the music sector, in which live events have become the major source of income, the requirement for bands and artists to go on tour to generate income has seen a significant growth in the scale and frequency of tours. This is true of small and emerging acts working to build a following, just as much as it is of mega-artists. At the largest scale, acts will have multiple stage set ups (U2's 2017 tour had three touring stage sets each requiring 16 trucks), enabling complex stage production involving stage build times of several days, whereby one stage is moving, one is building, and the other is being used for the show. In addition, 30 trucks worth of lighting, sound, and stage production traveled from stage to stage. This level of complexity requires highly sophisticated logistical control and large numbers of personnel (again U2 in 2017 had a touring crew of 196 traveling on nine buses) and a significant industry of expert tour managers and operators has developed as a result.

In addition, specialist suppliers will regularly "parachute" in to an event location on another continent, highlighting the global nature of the events industry and the impact that such transport logistics has on sustainability issues arising from events, especially in terms of air travel.

Transport Economics and Events

In addition to the important logistical considerations relating to the various transport-related aspects of delivering events, it is important to consider the impact that this will have on both the business model of event organizers and the impact on the wider economy. Transport economics aims to provide a means of understanding individual, business, and wider decisions about transport decisions and in the case of events this will most clearly be seen in terms of understanding the relationship between travel distance and cost incurred by attendees and the costs of staging in terms of venues and travel costs incurred in event staging. A successful event business model will seek to manage the ability of a chosen venue to deliver an excellent event experience alongside the willingness of attendees to travel the required distance to access the show and the cost of transporting equipment and personnel to the site.

Sustainability

Environmental concerns are increasingly recognized in the events industry; as events bring people together, they are heavily dependent on resources, impacting on the environment (Jones, 2017; Powerful Thinking, 2015; Raj and Musgrave, 2009). Events can generate significant waste, and put pressure on local resources such as transport and energy. As an example, it has been estimated that audience travel alone accounted for 80% of the carbon footprint of UK music festivals. The quality benchmark, Sustainable Events ISO 20121, published in 2012, was developed by the events industry to provide an international quality standard for events management, and all event supplier organizations can be accredited (ISO, 2012). Obvious solutions for event transport would focus on the use of local public transport. However, many events, such as music festivals, are often held in less accessible places with no public transport links. A UK music festival, Greenbelt, undertook research into how people arrived at the festival, observing the type of vehicle and the number of occupants, as they arrived for the start of the festival, using the format in Table 1.

Subsequently, festival organizers were able to encourage car-sharing as one method of improving overall sustainability. Other festivals included coach transport in the price of the festival ticket, with access to the site limited to official coaches, whilst other festivals developed specialist online programs for attendees to share cars and offer lifts. Some event organizations develop carbon-offset programs to support sustainability aims.

Illegal Events

Whilst the events industry and event management studies are mostly concerned with legal events, there are lessons to be learned from illegal events such as raves or freeparties, where the logistical planning process remains hidden and secret, until the night of the event, when there may be as little as a 1-hour window for event communication to take place (Dowson et al., 2015). In planning a rave, organizers select a venue for its hidden nature, using out-of-the-way outdoor countryside locations or urban abandoned buildings (and sometimes, not-so-abandoned buildings). The continuous search for new venues is an activity that runs alongside daily life, interspersed with regular forays that build complete familiarity with a chosen site, often undertaken under cover of darkness, and, almost inevitably, involve some form of subterfuge to ensure that the location remains undetected.

Table 1 Format for counting arrivals at Greenbelt Festival

Observation #	Minibus	Type of vehicle	Truck	SUV	Passenger car	Van	Motor home
# of occupants	1	2	3	4	5	6	6+

until the last moment. The secretive arrangement of logistics is paramount to the success of such an event. Transporting sound equipment to the depths of a forest or into the bowels of an abandoned warehouse without arousing suspicion of neighboring residents or the authorities is quite a feat. Facilitating the transport of thousands of people to arrive at the same time in a location that may be far from anywhere or in the middle of a city, with an hour's notice, is an accomplishment that many conventional event organizers would envy. Having the foresight to hide the trucks that delivered the sound systems a mile from the event location underneath a motorway flyover, to avoid confiscation by police, demonstrates skilful and well-considered planning processes.

Car Parking

Car parking for events offers a choice between self-regulated and controlled parking. A city-center event venue may rely on external car parks in the vicinity. Self-regulated parking in an unstructured and unmarked space such as a field requires minimal event staff but is less efficient than planned parking, so more space is required and problems arise if everyone arrives or leaves at the same time. A controlled car park is more efficient but requires large numbers of staff at entry and exit times. Car park requirements include marshals to direct traffic, adequate signage and signposting, and a numbered reference system for drivers and passengers to find their cars at the end of the event. For events that take place at night, adequate lighting is important along with considerations around safety of pedestrians (who may or may not be intoxicated). Specialist businesses exist to manage car-parking arrangements for large events, whether in permanent locations (such as sports stadia) or open fields (SEP, 2019; TRACSIS, 2019). Links to road networks are essential, and for larger urban events it is worth using several separate car parks that link to different parts of the road networks to avoid or restrict queues and congestion. Event car parks should include a separate entrance and exit, and a managed holding area with space for vehicles to turn in for drop-offs.

Public Transport

Public transport links aid the accessibility of event venues and enable a wider attendance. Some events specifically choose a venue due to its proximity to bus, coach, train, and underground stations. Factors to consider within public transport hubs include: effective signage (e.g., saying which bus is going where), space for safe queuing, boarding, and alighting of passengers, addressing capacity issues (e.g., are additional buses or trains needed), accessibility, station and platform capacities, stewarding and signage at bus or train stations, and the impact on existing services. The Purple Guide advises event organizers to consult with transport authorities about introducing new or enhancing existing services to service an event. Negotiations with train operating companies might include the need for bigger trains, extra, or later-running services.

In the United Kingdom, event traffic management comes under the requirements of The Road Traffic Act 1984, as inserted by the Road Traffic Regulations (Special Events) 1994. For large-scale events, traffic planning and implementation should take a multi-agency approach, working with traffic authorities such as the highways agency (for trunk roads) and the local authority (for other roads), the emergency services (police, fire, ambulance, etc.), local bus companies and businesses on routes taken by event participants, local car park operators (if separate from the venue), local residents, hospitals, travel assistance organizations (e.g., Automobile Association, Green Flag), and the media. Advance warning should be given of events and advance warning notices displayed.

Biographies

Rev. Ruth Dowson has been a Senior Lecturer at the UK Centre for Events Management at Leeds Beckett University, United Kingdom, since 2007, and was previously an events professional with 25 years' experience in the events industry. She holds an MBA from Bradford University School of Management, United Kingdom (1985), and an MA in Theology and Ministry from the University of Sheffield, United Kingdom (2013). Ordained in the Church of England in 2012, her research combines her passion for church and events. Her published research interests focus on events and church, the eventization of faith, venuefication, and the use of religious buildings for events. She is also co-author with David Bassett, of "Event Planning & Management," now in its second edition, and is a Fellow of the Higher Education Academy.

Dan Lomax has been a Senior Lecturer at the UK Centre for Events Management at Leeds Beckett University, United Kingdom, since 2010 following a varied 20-year career in music event production and management. He holds an MSc in Events Management from Leeds Metropolitan University (2003) and an MA in Transport Economics from the Institute of Transport Studies at the University of Leeds (1995). His research focuses on entrepreneurialism, business, and the economics of the Live Music Industry, and published work includes studies of both music festivals and music events. He is a Fellow of the Higher Education Academy.

Introduction

Reverse Logistics (RL) capabilities within a firm and across the supply chain act as “drains” that purge waste and allow fresh product to take the place of old and bad product. RL systems bring product back from forward positions in the supply chain and move those items to locations where they may be resold or disposed of properly at a minimal impact on the environment. These “drains” are tasked with cleaning the unwanted product out of the network while contributing as much as possible to profitability (Rogers et al., 2013a). In order for these drains to function as effectively and efficiently as possible, the RL system must make strategic use of the “secondary market,” the network of buyers and sellers who specialize in merchandise that is not suitable for sale in the primary retail market.

Over 100 years ago, both Sears & Roebuck and JCPenney became successful retailers when they introduced “no questions asked” returns. They realized that this was the best way to keep loyal customers, and offered them cash. Both evolved from very simple roots to become retail powerhouses. Sears started in a small train station in Minnesota, while JCPenney began as a tiny general store in Kemmerer, Wyoming. Both of these retailers utilized a unique business philosophy, which included open, liberal return policies where consumers could bring products back with no penalty (Rogers et al., 2013a).

This innovation, which was designed to increase customer satisfaction, formed a risk-free relationship for their customers. This meant that their stores were likely to keep long-term customers because the risk associated with shopping there was reduced. It was safe to buy something from Sears or JCPenney because the consumer knew that if it did not function well, or it was the wrong size, or it just did not work, they could return the product and get their money back. For these two pioneering retailers, taking back products from consumers was a smart marketing move that over the years consistently translated to business success. This realization was the beginning of the investment in developing RL processes to handle the returned material.

Definition of Reverse Logistics

RL has been defined as: “The process of planning, implementing, and controlling the efficient, cost-effective flow of raw materials, in-process inventory, finished goods and related information from the point of consumption to the point of origin for the purpose of recapturing value or proper disposal” (Rogers and Tibben-Lembke, 1999a, 1999b). Forward logistics is concerned with the flow of product from the point of production toward the point of consumption. RL is concerned with product flowing in the opposite direction, which leads to many important differences. Materials in the reverse flow are moving toward another use, or disposal. Although retailers have long understood the importance of strong forward logistics networks, retailers were much slower to appreciate the importance and competitive benefits of a strong RL network (Carter and Ellram, 1998; Dowlatshahi, 2000; Rogers, 2011; Wang et al., 2017).

Strategic Importance of Drains

One important function of RL networks is to serve as a drain for the firm, a place to get rid of unneeded or unwanted products. Biological systems have processes for ridding themselves of waste material and retail systems need the same. By removing unwanted products from the network, RL processes allow a retailer to ensure that the product selection remains fresh and current, full of product that customers want to buy.

Many categories of customer products including clothing, beauty products, and housewares, have significant annual seasonality. At the end of a selling season, the firm must have a way to remove unsold product from its shelves, to make way for the next season’s products. With an RL network, the firm can place the unsold products into the network to quickly and easily remove all unsold products from their network. Without an RL network, the only way to get rid of unsold product would be to mark it down repeatedly, which would have bad consequences. Companies may over-estimate demand for a product, or market conditions may change, or other factors may lead to an over-abundance of an item. Drains also provide the retailer with the opportunity to dispose of these unwanted items. Retailers invest heavily to create a brand image, and stores filled with shelves or racks full of clearance-priced merchandise would not make a positive contribution to their brand. Retailers already offer a series of increasing markdowns toward the end of a selling system. If the product stayed behind after the end of the season, it would only further train customers to wait for better prices. Repositioning those items to an alternative distribution channel can be a better strategy so that consumers buy fresh product from their original destination.

Reverse is Different

As mentioned in the introduction, RL processes are different than typical forward logistics processes and systems. The processes required to manage RL are more complex than those needed to manage the forward flow of fresh product, while at the same time the amount of product in the reverse flow is smaller. In Table 1, some of those differences are identified.

Overview of Reverse Logistics Activities

RL networks perform a variety of important tasks. For a retailer, a product may enter an RL network for different reasons, and from different positions. From a retail location, a product may be returned by a customer, or put into the network by the retailer directly. For a customer return, where the consumer brings an item back to the retailer or ships it through the post to the ecommerce retailer, an assessment must be made of the condition of the item, and the disposition destination must be selected. In fact, RL systems that include predetermined dispositions are almost always better than taking the decision about where to send the item after it arrives at the place where it is being sorted.

Table 1 Differences between forward and reverse

<i>Forward</i>	<i>Reverse</i>
Product quality uniform	Product quality not uniform
Disposition options clear	Disposition options unclear
Routing of product unambiguous	Routing of product ambiguous
Distribution costs easily understandable	Distribution costs less understandable
Pricing of product uniform	Pricing of product not uniform
Inventory management consistent	Inventory management not consistent
Product life cycle manageable	Product life cycle less manageable
Financial management issues clear	Financial Management issues unclear
Negotiation between parties straightforward	Negotiation less straightforward
Type of customer easy to identify and market to	Type of customer difficult to identify and market to
Visibility of process transparent	Visibility of process less transparent

Source: Modified from *Tibben-Lembke and Rogers (2002)*

Product may be placed into the RL network directly from the retailer. This is especially true with ecommerce returns that are sent by the consumer directly to a processing facility. A retailer may have too many units of an item at one location, and use the RL network to reposition the items from a place of low demand to one of high demand. A retail item typically enters the RL network via the service desk at the store. At the service desk, the items are scanned and a disposition decision is typically made, particularly regarding whether the item will be sold at the current location, or sent elsewhere.

For a manufacturer, RL activities primarily consist of selling off unwanted new product. Because of economies of scale, a manufacturer may produce a larger batch of product than they have orders for. If enough additional orders are not received, the firm will have product that they may want to sell off. A similar situation arises when a large customer order is cancelled.

Strategic Use of Returns

For most retailers, the largest source of unwanted items is customer returns, but there are many reasons products enter the RL network.

Retail Return Rates

Return rates for general merchandise retailers in the United States are typically around 6%. This number has stayed fairly constant over recent decades. In fact, books about retailing in the 1950s also give this number as being typical. The rates are typically much higher for clothing, easily reaching 20% or higher. For ecommerce retailers, the typical return rate is much higher and for some products can range between 10% and 30%.

Lowering Transaction Risk

Returns may seem like an undesirable condition that should be avoided as much as possible. However, returns are actually very important and can become strategic. By making it easy for customers to return items, retailers lower the transaction risk of doing business with the retailer, which makes it easier for the customer to purchase from the retailer. As previously described regarding Sears and Roebuck and JCPenney, lowering consumer risk is a key benefit of a liberal returns policy.

Changing Policies

Companies would like to reduce the volume of returned product they must deal with, but they are well aware of their strategic benefits. However, companies have experimented in recent years to see what types of restrictions customers would accept. In the 1990s, Nintendo created a technological solution that allowed them to capture the serial number of each gaming console as it was sold. In addition to the serial number, the system also recorded the date and the retailer selling the item. If a customer tried to return the item to a different retailer, or outside of the allowable returns window, the system would prevent it. Nintendo spun the business off into a separate company called Siras, which is now part of InComm.

Their technology allowed Nintendo to avoid a very serious form of returns abuse. When a new gaming console system came out, customers would return consoles of the previous generation, and falsely claim to have purchased the unit recently, within the returns window, and Nintendo had no way to dispute that claim. Because the new system merely provided a way for Nintendo to enforce an existing policy, there was little customer push back.

Table 2 Types of returns

<i>Return types</i>	<i>Attributes</i>
Consumer returns	Returns to the retailer from consumers due to buyers' remorse or defects. This category is generally the largest returns grouping.
Marketing returns	Product returned from a position forward in the supply chain often due to slow sales, loading the trade, or the need to reposition inventory.
Damage returns	Returns of product to the manufacturer driven by the retailer's choice but not by the consumer. These are different from marketing returns in that the items are not first quality product because they were not checked carefully prior to shipment, or more likely, they were damaged in transit. These items may be returned to a reclamation center and then the cost is deducted from the manufacturer's invoice.
Asset returns	Recapture and repositioning of an asset such as reusable pallets, racks, or totes.
Product recalls	Usually initiated because of a safety or quality issue. Requires planning security. May be voluntary or mandated by a government agency.
Environmental returns	The disposal of hazardous materials or abiding by environmental regulations.

From its founding in 1912, LL Bean had a lifetime, no-questions-asked returns policy. In 2018 it changed the policy to one year, unless the item is defective, because too many people were abusing it. People were buying damaged old items at garage sales, and returning them for new products, which they then sold. Although a majority of customers accepted the policy as reasonable, there have been unsuccessful lawsuits challenging the policy.

Omnichannel Synergies

Although online shopping typically has a higher returns rate than in-person shopping, retailers have simplified the returns process by allowing customers to return the item directly to a store, instead of having to mail the product back in. This is often easier for the customer, and it brings the customer into the retail store, where the retailer hopes the customer will purchase a replacement item or additional items. This is one more way that returns can offer a competitive advantage. In 2017 Amazon purchased Whole Foods, and one of the services they began to offer was the ability to return items at Whole Foods stores, no shipping required.

In July, 2019 Kohls department stores announced a partnership with its online competitor Amazon, in which Kohls allows customers to return Amazon items at Kohls stores. In its limited trial before rolling out the program nationwide, Kohls said stores accepting Amazon returns saw sales growth of 8%, compared to 2% growth for the rest of their stores.

Types of Returns

There are several types of returns. It is not enough to merely know that returns are being generated. It is important that managers be aware of the source and type of return they are receiving. They should also understand the reason for the return. A firm needs to develop different strategies and systems to deal with each type of return (Table 2).

Centralized Returns Centers

If a retailer determines that an item is not to be sold in the store and needs to be sent elsewhere, it is frequently sent to a Centralized Returns Center, or CRC. At a CRC, employees have training and experience in assessing the quality of the items. They also have access to information systems about the number of units of different quality already available.

CRCs are used because companies have learned that it is unwise to process returns at a forward distribution center. Trying to do both in one facility creates the problem of "serving two masters." The primary focus of a forward distribution center is delivering new product to stores, in large volumes. Forward logistics supplies product that provides the firm with revenue. RL represents a cost. When things get busy and labor is constrained, as it always is, DC managers are likely to allow returns management to be ignored.

Also, the processes for forward and reverse goods are entirely different. An arriving pallet of new product is all in identical boxes, clearly labeled, and the products are interchangeable. RL is, by definition, exception-driven. When a pallet of returns arrives, it will contain many different products, some with packaging, some without. Some of the advantages of a central location to manage returned product are the following:

- An important factor for success in RL is the speed of processing. CRCs can help companies increase the speed of processing returns. As one industry professional observed, returned goods are not like fine wine. They do not get better with age.
- Because the items often lack original packaging, the more times they are moved around a facility, the more likely they are to become damaged. Quickly deciding what to do with an item and getting it out of the facility reduces the opportunities for damage.
- If an item has been discontinued or in some other kind of shelf pull, the sooner the item is disposed of in the secondary market, the better the likelihood of receiving a higher price for the units.

Disposition Decision-Making

A key part of RL is deciding which disposition to choose for an item, what the destination of the material should be. Every item must be carefully evaluated, to find the most valuable destination for it. Without a strong RL network, a retailer would be forced to landfill all unwanted product. Such a retailer would lose out on millions of dollars of potential revenues, which could easily make the difference between profitability and loss. Selecting the proper disposition option has important financial implications, therefore, and knowing the amounts that could be received for each potential option is a critical part of this selection.

In addition to different potential amounts of financial return, different disposition options also provide the seller with differing abilities to control where the product is resold, and the prices at which it is resold. Maximizing financial payments are an important consideration, but often these are secondary to being able to protect the value of the brand.

Disposition Options

The possible destinations for a product that has entered the RL network include the following, generally listed in order of decreasing revenues:

As New

If the item is unopened and can be sold as new, the retailer may be able to still make a profit on the item, but not as great as before. The original retail profit margin takes into account the cost of buying, transporting, displaying and selling the item. Accepting the item as a return and placing it back on the shelf does add labor cost, but most items still generate a positive profit.

Open Box—New

An open box item has been opened, but is still in new condition. However, most customers would expect to receive a discount off the original retail price.

Open Box—Returned

If an item has been opened and returned, it cannot be sold as new. Some retailers may be able to inspect an item to ensure it still performs to specifications and sell it, but at a greater discount off the original retail price. The value received will be determined by the condition of the item.

Refurbished to New Standards

Some items may require some repair or refurbishing before being resold. Refurbishing can be completed by the original manufacturer, by third parties contracted by the manufacturer, or by outside companies who purchase the items in the secondary market.

Refurbished, Cosmetic Imperfections

Sell as refurbished, but perhaps cosmetically inferior to new products. The value will be significantly influenced by the level of cosmetic imperfections.

As Is

An item sold “as is” may be fully functional, or perhaps not functional. Anyone buying such a product is accepting all of the risk of the transaction. Because most buyers do not have the knowledge or materials to repair most items, they would expect to receive a very large discount in compensation for accepting this risk. As with the related category of open box, the value is heavily influenced by the condition and degree of functionality of the item.

Sell to Secondary Market Broker

As described further, the secondary market is the term for all of the brokers and retailers who buy and sell product outside of the primary sales channel. When a retailer sells to a secondary market broker, the product may change hands multiple times before being sold to a retail customer. As the products pass between brokers, more detailed diagnostics will be performed on the item, and where economically feasible, repairs will be made and the item sold as refurbished.

Table 3 The 10 biggest product recalls

<i>Rank</i>	<i>Recall</i>	<i>Cost (as of March 2018)</i>
10	Tylenol	\$0.1B
9	Peanut Corp. of America	\$1.0B
8	Toyota Floor Mats	\$3.2B
7	Pfizer's Bextra	\$3.3B
6	General Motors Ignition Switches	\$4.1B
5	Samsung Galaxy Note 7	\$5.3B
4	Firestone Tires and Ford	\$5.6B
3	Merck's Vioxx	\$8.9B
2	Volkswagen Diesel Engines	\$18.3B
1	Takata Air Bags	\$24.0B (and counting)

Component Harvesting

If a product cannot be refurbished profitably, instead of disposing of it in a landfill or recycling any recyclable components, there may be major components such as computer boards, semiconductors, motors, etc., that can be removed and used or sold as replacements.

Recycle/Recover Primary Materials

If there are no components that can be harvested, or after any have been harvested, any metals, plastics, or glass materials can be recycled. The value of plastic or glass recyclables is generally quite low and depends on market conditions, which often depend on global trade realities. Metals, however, can be significantly more valuable. In some cases, then, the firm can receive a payment for the recyclable materials, or pay a lower cost for disposal than for mixed waste when landfilling.

Landfill

The very last option for any product is the landfill. All other options offer at least the possibility of some payment. If a product is sent to the landfill, the firm not only loses all of the investment it made in purchasing and processing the product, it now must pay someone to take the product away and bury it in a landfill.

Recalls

There are a lot of reasons for a product to be recalled, but typically they involve a liability issue. Some are mandated by a consumer product agency or the Food and Drug Administration. Faulty parts generally occur in two places along the supply chain: Either the product's original equipment manufacturer or at the facility that assembles the product (**Table 3**).

Traditional recalls often involve items at the consumer or the last step before the consumer, but it can be anywhere. For this reason, recalls are a major concern for supply chain managers. Recalls are split about evenly between voluntary and mandatory. When a product is recalled, the company has a responsibility to ensure that all potentially harmful products are removed from circulation. This means that all of the items should be collected and either destroyed, or retrofitted in such a way as to prevent anyone from being injured. This collection, destruction and refurbishing is an important RL function. Unlike typical customer returns, which come in gradually, however, recalls come in a short period of time, and may require that dedicated teams be created to process them.

Food Recalls

Many recalls represent significant risks to the public. In 2018, according to the US Department of Agriculture, 20.6 million pounds of food (10,000 tons) were recalled in 2018. Salmonella accounted for nearly 13 million pounds alone. Companies are working hard to stop recalls from becoming necessary, but given the complexity of today's global food networks, this will be difficult. This is why companies are also working hard to reduce the scope of any required recalls.

Current recalls involve such large volumes of product because companies have very limited visibility of exactly where products from a given production lot end up. Companies are working hard on technological fixes, such as blockchain, to provide better reporting. Despite the numerous headlines about blockchain, it is, in the end, merely a secure method for storing databases. The real obstacle to more limited recalls is the tracking of where products come from and where they have gone to. Technologies for tracing products throughout the distribution channel must be improved before recall volumes will be reduced.

Unsaleables

Crushed cans, rumpled boxes and expired cartons—“unsaleable” products continue to create challenges for the food and consumer product industry up and down the supply chain. A new GMA report on unsaleables costs and business practices shows that unsaleables are still on the rise, costing the grocery industry \$4.2 billion in 1998—up from \$4 billion in 1997. Pharmacy chain retailers such as Boots or Walgreens experience a much higher return rate than other channels, while mass merchants and club stores, such as Costco, generally experience much lower unsaleables rates than average.

When Walmart moved to open code dating and most retailers followed their lead, unsaleables increased dramatically. Every food or pharmaceutical product typically has an expiration date. In 1997 Walmart began to ask their suppliers to place expiration dates on the consumer package as “open codes” that consumers would be able to easily read. Before 1997 most expiration dates on consumer packaging were in a format that was unclear to consumers. Because of these changes, manufacturers went to reduce shelf life, so that consumers would not know how long the shelf life was. Some reduced shelf life by 90%. An example of how these changes impacted brand owners is Campbell’s Soup. They manufactured cans of condensed soup with three years shelf life. When Walmart asked them to go to open date coding they had 2 years of shelf life before the expiration date occurred. After open code dating, Campbell’s decided to move to 90 days of shelf life for marketing reasons. These changes have caused large problems for the industry.

Secondary Markets

Secondary markets effectively act like efficient drains that are supplied through RL systems. Having “drains” that can carry unwanted product to places where it can be resold is an important method for reclaiming value where it could otherwise be lost. The product sold into to the secondary market is generally being sold for less than its original price, so it might seem surprising to speak about RL systems contributing to profits (Tibben-Lembke, 2004).

As described further, to monitor progress in its RL processes, a company should measure the financial impact of returns on the firm and on other members of the supply chain. This can include measuring aspects of RL such as material scrapped and products resold through secondary markets that can reclaim value.

Description of the Secondary Market

Secondary markets have become a significant portion of domestic economic activity in the United States. Many companies recover, refurbish, remanufacture, and recycle product for additional use elsewhere instead of throwing the product away. Secondary markets act as system “drains” where excess inventory or assets can be recovered and resold.

The secondary market consists of retail store returns, surplus inventory, bankruptcy sale inventory and products that did not sell the first time around. It includes firms that specialize in buying close-outs, surplus, and salvage items. The secondary market firms then sell the product through their own stores or to other markdown retailers, such as dollar stores. The secondary market is fueled by the RL processes in a supply chain. eBay is the biggest player in the secondary market and many of the items for sale there are company returns.

As described above, RL flow is very different from the forward flow. Reverse flows are more reactive, with much less visibility. Because any supply chain may have product flowing in the reverse channel, the range of RL and secondary market development issues facing a particular supply chain will be as diverse as the number of supply chains.

Financial Issues

Another issue in examining RL practices is that the accounting methods that most firms use to manage their business are designed to manage the business in forward distribution. The costs and processes related to managing product that is moving backwards through the supply chain and being dispositioned to a secondary market typically do not show up neatly in an easily understood package in a firm’s balance sheet or income statement. In forward logistics, costs are usually well defined and well known.

Accounting systems are built to handle the comprehensive cost development for a product as it moves through the forward channel. The systems used for accounting for RL are more specialized, even if straightforward. Firms specializing in forward logistics are usually not very effective at managing the amount of detail derived from a product’s non-standardized journey backwards through the firm and the channel. For example, transportation costs on a firm’s income statement may be derived from both forward distribution and RL.

Disposition Decision-Making

Additionally, when deciding how to dispose of product or select the appropriate secondary market, there are a variety of options. Unlike forward distribution, RL managers may need to spend significant time determining where a particular item will be shipped because the condition of the item must be considered, as well as any agreements with the manufacturer regarding disposition. Manufacturers often have strict requirements about where product can be sold into the secondary market. They want to ensure that

the product is not advertised or sold any place that could potentially damage the brand equity. Therefore they often place significant restrictions on firms' secondary market activities.

Given the range in returned product quality, variations in pricing are to be expected. While the prices of products in the forward channel can vary due to factors such as value-added services or total quantity purchased, the pricing variability of returned products can be even more complex. Making quick disposition decisions into a particular secondary market can improve the profitability of selling into that secondary market.

Secondary Market Size

In 2018 the size of the secondary market in the United States was estimated to be approximately \$618 billion. This number was about \$100 million larger than the total amount of ecommerce revenues in the United States. (Rogers et al., 2010). The secondary market reduces waste and provides a stable income for a growing sector of the US economy, providing jobs for millions of workers around the world. Salvage products are not only an important part of the domestic economy, but they also make up a significant portion of US exports.

US consumer returns are estimated to exceed \$100 billion per year. This estimate is larger than two-thirds of all countries' total Gross Domestic Product (GDP). To illustrate the size of the market, Walmart is estimated to have processed over \$12 billion in consumer returns in the United States during 2009.

Secondary Market Flow

In this section, the reverse flows that feed various secondary markets are depicted. Fig. 1 includes the major secondary markets through which consumer electronics flow. The appropriate secondary market and disposition route depends on the type of product, its desirability in the marketplace, condition, and demand levels. As depicted in Fig. 1, there are several definable secondary markets for returned materials.

Fig. 1 reflects the complexity of the secondary market. The journey from asset recovery to its final destination is often filled with many twists and turns. The route to the secondary market consumer is not necessarily an efficient one.

Researchers have divided the secondary market into meaningful segments. These segments are as follows:

- Retailer,
- Manufacturer,
- International disposition,
- Auctions,
- Salvage dealers,

Figure 1 Structure of the secondary market.

- Factory outlets,
- Pawn shops,
- Dollar stores,
- Flea markets
- Charities, and
- Value retailers.

As the product flows from one level of the secondary market to the next, the dealers incur shipping and handling costs at each level of roughly 8%, and receive a profit margin of roughly 10%. The dealers purchasing directly from retailers typically purchase at a cost of approximately 15% of the original wholesale cost of the item. The price increases to approximately 18% for the Level 2 Salvage Dealers and 21% for Level 3 Salvage Dealers.

Total US Secondary Market

Summing the totals from each secondary market segment gave a conservative estimate of over \$618 billion in the United States for 2018. Without the secondary market to efficiently wick away product that cannot be sold through a primary market, many of these goods would be thrown away. It is useful to understand the size and structure of this market because of its environmental, social and economic impact. The secondary market provides environmental and social benefit, and is a significant portion of the US economy. In [Table 4](#), the various segments are compared.

Secondary Market Relative To GDP

Clearly, the secondary market is a large portion of the US economy. The methodology to estimate the size of the secondary market is deliberately conservative. The secondary market in the United States was estimated at \$618 billion in 2018, which represents more than 3% of US 2018 GDP. The concept of GDP has been defined to be “The market value of final goods and services newly produced within a country’s borders within a fixed time period.” This means that much of the value of the secondary market, as defined here, does not show up as a final good or service and is not included in GDP. Items that are not part of retail sales or the final step of a supply chain in an alternate channel are ordinarily not included in US GDP calculations.

Reverse Logistics Metrics

As with all other supply chain activities, firms are increasingly finding ways to measure and track the performance of their RL activities. Typical RL metrics are included in [Table 5](#).

Value of Returned Product

There can be several moderating factors on the pricing of product. Inventory levels, whether the product is current or at the end of life and seasonality all impact secondary market pricing. For example, in October a higher price can typically be gained than in March when retailers or manufacturers are more likely to be dumping product. If the market has a glut of a specific type of product, or a product is near the end of its lifecycle, the return from selling a product in the secondary market is likely to be lower. Also, product quality can be a factor in pricing. If the item is perceived to be a low-quality product or it is damaged in some way, then the likely return will also be lower.

Table 4 Size of the secondary market

<i>Sector</i>	<i>2018</i>
Factory outlets	\$48,439,708,714
Value retailers	\$59,192,930,000
Online auction houses	\$159,300,000,000
Dollar stores	\$38,769,174,400
Salvage dealer	\$230,861,990,000
Pawn shops	\$25,943,730,000
Flea markets	\$38,201,625,000
Charities	\$17,912,235,000
Total US secondary market	\$ 618,621,393,114

Table 5 Typical reverse logistics metrics

Dispositions
Amount of product to be reclaimed and resold
Percentage of material recycled
Freight costs and fuel utilized in transportation of returns
Handling costs and energy used in handling returns
Waste
Recycled materials
Total cost of ownership
Credit reconciliation
Transformation and repair decisions
Zero returns
Channel conflict
Declining product values
Time to cash
Store efficiency
Exploitation of vendor agreements
Maximize recovery

The type of consumer electronic product can impact pricing. For example, large flat screen televisions are likely to have a different depreciation curve than cell phones. Different brands of the same product can depreciate at diverse rates.

Conclusions

For firms selling product around the world, solving the problems of managing returned items and RL processes is critical to their ongoing success in an environment where consumers have become more demanding around the world. Understanding how to implement best RL practices is something that all supply chain managers need. It is important that managers can both efficiently ship new products and manage returned products that have entered the reverse flow.

Biographies

Dale Rogers is the ON Semiconductor Professor of Business at the Supply Chain Management Department at Arizona State University. He is also the Director of the Frontier Economies Logistics Lab and the Codirector of the Internet edge Supply Chain Lab ASU. Dale is the Leader in Supply Chain Finance, Sustainability, and Reverse Logistics Practices for ILOS—Instituto de Logística e Supply Chain in Rio de Janeiro, Brazil. In 2012 he became the first academic to receive the International Warehouse and Logistics Association Distinguished Service Award in its 130-year history. He is a Board Advisor to Flexe, Enterra Solutions and Droneventory and is a founding board member of the Global Supply Chain Resiliency Council, Reverse Logistics and Sustainability Council and serves on the board of directors for the Organización Mundial de Ciudades y Plataformas Logísticas.

Dale is a Leading Researcher in the fields of reverse logistics, sustainable supply chain management, supply chain finance, and secondary markets and has published in the leading journals of the supply chain and logistics fields. He has been Principal Investigator on research grants from numerous organizations. He is a Senior Editor at the *Rutgers Business Journal*, Area Editor at *Annals of Management Science*, and Associate Editor of the *Journal of Business Logistics* and the *Journal of Supply Chain Management*.

He has made more than 300 presentations to professional organizations and has been a faculty member in numerous executive education programs at universities in the United States, China, Europe, and South America as well as at major corporations and professional organizations. Dr. Rogers has been a Consultant to several companies and a principal investigator on research grants from numerous organizations and is the author of a new book on the subject of Supply Chain Financing along with Rudi Leuschner and Tom Choi.

Ron Lembke is an Associate Professor and the Chair of the Managerial Sciences department at the University of Nevada. He is the Chair of the Standards Committee of the Reverse Logistics Association where in 2016 they established a new ANSI approved standard for including multiple pieces of product information in a single 2D barcode, which has been assigned the 12 N designator, and is also known as Standardized QR for Logistics. Ron has been at the University of Nevada since 1995.

Introduction

E-tailing is short for electronic retailing and basically refers to the sale of goods online. E-tailing has increased substantially over the past 10 years and now accounts for over 10% of sales of most categories of product (and substantially more for some categories). In 2017, Statista.com states that global e-tail sales amounted to US\$2.3 trillion, up from US\$1.3 trillion in 2014, and that 1.7 billion people worldwide shop online. When we talk about e-tailing, the discussion is often confined to the sale of consumer goods, that is, business-to-consumer (B2C) sales. It is important, however, to also include business-to-business (B2B), and consumer-to-consumer (C2C) sales in the case where the purchaser is the final consumer. In China, e-tailing is sometimes referred to as O2O (online-to-offline). The term e-tailing is sometimes used synonymously with e-commerce. Strictly, however, e-commerce is a more general term that refers to all electronic communications, so includes things like e-mail and electronic document transfers. When looking at statistics, it is important to pay attention to the precise definition used by the data source (Cullinane and Cullinane, 2018).

E-tailers can be divided broadly into those, which only sell products online, termed “pure e-tailers” and those which have both an online and a physical store presence, termed “mixed retailers.” Both “pure” and “mixed” e-tailers own the stock of products, which they sell. A third and increasingly important category of e-tailers are the so-called “market places” of which e-bay and Alibaba are examples. Such companies advertise and sell the products of other companies and generally do not own the stock that they sell. Some companies, such as Amazon and Zalando are hybrids: Amazon sells some of its own products; it sells products, which it has bought from other retailers and acts as a marketplace for other retailers. Zalando sells its own products and acts as a marketplace for other retailers. The e-tail sector is certainly dynamic and difficult to categorize as new formats and channels appear and disappear.

E-tailing is often referred to as being multi-channel or omni-channel. The difference between the two is that multi-channel refers to the fact that an item is available through more than one channel (e.g., online, in store, in a catalogue or maybe through a television channel), whereas omni-channel refers to the case where a customer uses more than one channel to purchase a product (Saghiri et al., 2018). An example of an omni-channel purchase is one where a customer has looked at a product in a shop and then purchases it online.

The logistics associated with e-tailers is sometimes referred to as e-logistics and an e-supply chain can be very complex, involving many links, for example, B2B2B2B2C. In some respects, the logistics associated with e-tailing is much the same as that required for traditional retailing; the major difference is that rather than servicing physical retail outlets (stores), the logistics operations are geared towards servicing the final, individual customer. This so-called “last-mile” delivery (i.e., delivery from a hub to the final consumer) is the problematic element of e-logistics as instead of servicing a fixed number of often quite large stores with well-organized and efficient goods-receiving procedures, companies are dealing with millions of individual people, each with their own delivery requirements and expectations and with little appreciation of the logistics involved. The last-mile delivery element costs e-tailers a disproportionate amount of money and is responsible for considerable environmental problems.

Operational Issues

Delivery Windows

The efficiency of last-mile operations is affected by the width of the “delivery windows.” A delivery window is the time-slot in which the parcel delivery company can deliver an ordered item to the customer. This is often chosen by the customer at the time of purchase and can range from a 2-hour slot (say between 10:00 and midday, or between 16:00 and 18:00) to half a day or even a full day. The customer usually wants the window to be as narrow as possible to increase the convenience to them, but for the delivery company, the wider the window the more convenient and the cheaper the delivery. Many delivery companies now notify the customer just before they arrive to maximize the convenience to the customer. Some delivery companies allow the customer to track the progress of their parcel and thus have a more precise knowledge of when their parcel will arrive.

Delivery Options

There are various delivery options used by customers. Delivery options can be divided into “attended,” where a person must be present to receive the item, and “unattended” where there is no requirement for the presence of a person. Unattended deliveries are in many ways preferable as it eliminates the “not at home” problem; this can mean increased convenience for the customer and means that deliveries can be made at a time suitable to the delivery company (including overnight for instance). Attended delivery options include delivery to the home or other location chosen by the customer (such as their place of work); delivery to a collection point of some description (such as a local shop or petrol station). Unattended delivery options include delivery to a doorstep or safe location around a person’s residence, to a locker in a locker bank (such as that used by Amazon), to a purpose-built reception box located outside a person’s residence, or even to the back of car (a solution which was trialed by Volvo). While in the United Kingdom, delivery to the home is the most popular; in other countries (such as Sweden) delivery to a collection point is more popular.

The usual means of transportation for the last-mile delivery is a van. The number of vans in circulation over the past 10 years has increased substantially as e-tailing has increased (although it cannot be stated categorically that one is a direct result of the other). There are many parcel delivery companies, all competing with each other and each with a slightly different method of operating and dealing with the customer. In addition to vans, and often in a bid to be more “environmentally friendly,” other delivery solutions have appeared, including motorcycles, pedal and electric bikes of various configurations, mini trains, taxis, and even trams. Drones are being piloted by several companies as are small ground-based autonomous pods. In more rural areas, the final mile is sometimes made by private individuals who pick up parcels from a hub and deliver them to customers in their private cars. This can save parcel delivery companies money and can also sometimes increase the proportion of successful deliveries. While all these alternative delivery methods can be useful, they also disguise the count of distance traveled in the course of parcel deliveries, once again casting doubts over the official statistics.

An increasingly popular option is “click-and-collect,” whereby the customer picks up their online purchase from a branch of the retailer or other collection point, or “reserve-and-collect,” which is the same as the previous option except the item still needs to be paid for when the customer collects the item ordered online. The attraction of these two options is that they are usually free for the customer (as opposed to home delivery which some companies charge for) and it means that the customer can collect the item at their own convenience rather than waiting around for a delivery at home. For the e-tailer it may also provide an opportunity for them to sell additional items when the customer collects their ordered items. It is a much cheaper option than delivering to the home because it eliminates the last mile element of the trip, including the redeliveries resulting from the unsuccessful “not at home” trips.

E-Fulfillment

From the e-tailer’s perspective there is a range of possibilities that can be used to fulfill customers’ orders (termed e-fulfillment). For mixed e-tailers, customer orders might be picked from the shelves of a nearby physical store. Supermarkets often fulfill at least some of their orders this way. In locations close to centers of high population, however, this method is not very efficient: it reduces the stock available for physical shoppers; the range of in-store stock might be substantially less than that available to the customer on the website and; the pickers (i.e., those employees who actually go around the shop making up the customers’ online orders) might interfere with the customers in the store. In such cases, companies might set up dedicated e-fulfillment centers (sometimes termed “dark stores”).

For products other than groceries, e-fulfillment normally takes place from a warehouse or distribution center. In the case of a mixed retailer, this might be in a dedicated e-tailing area within a warehouse containing the stock destined for the physical stores, or in some cases, it might be a dedicated e-tail warehouse. Where a company needs to dispatch a large volume of goods very quickly, the e-tailer might cut out the warehouse altogether and engage in what is termed “drop-shipping.” In this case, the e-tailer never touches the products, but the manufacturer or wholesaler delivers the goods direct to the customer. This is very prevalent in B2B e-tailing but is increasingly important in B2C e-tailing, particularly in the case of products which are required by the customer very quickly, where the manufacturer has logistics expertise which a parcel company does not have or where the goods are heavy and using a drop-shipper can reduce double handling.

As e-tailing has increased, customers’ expectations of delivery times have changed. There is an increasing desire for almost immediate delivery of products ordered online. In a bid to be competitive, companies are offering faster delivery times. Next-day delivery is an option in many cases and an increasing number of companies are even offering same-day delivery. In some cases,

customers are expected to pay for these super-fast delivery options, but not in all cases. Amazon Prime is an example where for a relatively small annual fee, customers can request next-day delivery as a “free” option for many products. In larger countries, such as Canada, Amazon offers two-day delivery. It can generally be said that the faster the delivery request, the greater the demands on the logistics operation. Fast delivery means that load consolidation is less possible, so vehicles are more likely to be running less-than-full. This increases the logistics costs, as well as the costs to the environment.

Cross-Border

The online market is truly global and one of the major developments over the past decade has been the increase in cross-border online trade. For many countries, cross-border trade accounts for more than 50% of online trade, with China and the United States being two of the main beneficiaries of this trade. This obviously impacts on e-tail logistics, making the logistics chains much longer and complex and increasing the propensity for goods to be transported at least in part by air.

Environmental Impacts

There is some debate over the environmental impacts of e-tailing. Some research has suggested that buying things online is less environmentally damaging than buying them in-store, whereas other research has shown the opposite. In order to properly calculate the environmental impacts of e-tailing, both individual travel behavior and freight transport must be taken into account. Some studies do not take into account the former. A problem arises in where to draw the boundaries of the calculations. For example, if a person does not drive to the shop to buy a product, then it might seem that this saves a car trip. But what happens to the car when it is not being used for the shopping trip? Will it be used by another member of the family for some other purpose or perhaps it will be used for another purpose by the person who would have made the shopping trip. And does the fact that shopping trips are not so frequent mean that there will be an overall impact on car ownership? On the freight side, the extent of environmental damage will depend on the drop-density of the load (i.e., the number of parcel deliveries per unit of distance traveled by the van). The higher the drop-density the lower the environmental impact per parcel. It will also depend on the traffic conditions in which the van is driving, the type of fuel used, the level of urbanization, the driving behavior of the van driver and many more things. How often when you order a set of 4 printer cartridges, for example, do they arrive in 4 separate packages from 4 different companies maybe at 4 separate times and with 4 lots of packaging? Several studies have shown that the level of packaging associated with e-tailing is much greater than that associated with shopping in store. It has also been shown, however, that the level of waste is greater for physical shops than it is for online shops, as physical shops often over-stock on some products which then need to be disposed of in some way. Finally, there is the issue of reverse logistics and the negative environmental impacts of this activity in e-tailing.

Reverse Logistics

Background

Reverse logistics refers to the flow of goods back from the consumer to the retailer or the manufacturer. It involves most of the logistics operations covered above, but in reverse. Consumers have always returned products back to stores but, in the case of e-tailing, the number and proportion of returns is much greater. There are many reasons why a customer might return a product: it might be damaged or faulty or the wrong product might have been delivered; it might not match the expectations the customer had from looking at it on the website; the customer might have ordered without much thought and subsequently changed their mind. However, many of the returns occur because of consumer behavior, which is almost specific to the process of buying online. Over-ordering is a key issue in this context. The consumer cannot try things on or see the product that they are buying, so they over-order and then routinely send back what they do not want. For example, a person may order a shirt in 4 different colors and 3 different sizes, try them on at home, perhaps keep one or two and send back the rest. Their home becomes the changing room. In addition to this there are levels of “wardrobing,” that is, purchasing a product, using it once or twice and then returning it and “renting” where a customer uses a product for a specific purpose (e.g., a camera for a birthday party) and then sends it back. There is also a level of totally fraudulent returns which might include purchasing a high value item and sending back a fake; falsely claiming that something is faulty in the hope of getting a refund and customers sending back random items hoping that a refund for their original purchased item will be made. This all adds up to the facts that return rates are often very high. In the clothing sector, which has the highest level of online purchasing, the returns levels are also the highest. Typically, the returns rate for clothing is around 22%, but it can increase to around 60% for high-fashion goods and even 90% for “occasion wear” such as evening wear. Consumer behavior is reinforced by the policy of e-tailers to offer free returns.

Reverse Logistics Costs

The logistics costs to e-tailers of dealing with their returns is very high, in fact it is around 3 times that of the outward logistics costs. Each return must be collected, transported, inspected, sorted, and repackaged before it can be put back into outbound stock. An item of returned clothing will need to be visually inspected and sometimes sniffed; it may need to be cleaned or hairs and fluff might need

removing. It might need re-ironing and then repackaging. Manpower and space is required for all these processes. Generally, it takes three times more manpower to deal with a returned item than to deal with the initial dispatch of that item.

Outward logistics is often extremely well-planned and efficient and often involves the delivery of large quantities of goods to a relatively small number of often well-organized companies. With reverse logistics however, the returns are being made from a very dispersed, large number of individuals who have little knowledge and often little interest in the logistics requirements of getting their product back to the retailer. These individuals may keep their item for 1 day before they return it or for 63 or 364 days. Obviously, the longer they keep the product, the less likely it is that the e-tailer can re-sell it, particularly at full price ([Ferne and Sparks, 2018](#)).

The e-tail market is very competitive and keeping costs as low as possible is crucial for e-tailers. High wages are a major cost factor in dealing with returns, so some e-tailers actually process their returns in low-wage countries. In Europe, for example, some clothing e-tailers process their returns in Estonia or Poland and then transport them back to warehouses in western Europe to re-dispatch the goods to new customers. This can result in returns being transported for many hundreds of kilometers. In environmental terms, this is not very sustainable. E-tailers are sometimes loathe to deter customers from making returns, as there has been research to show that those customers who return the most also spend the most; so by deterring returns, profitability might be adversely affected.

Stock Visibility and Availability

Two key issues in reverse logistics are stock visibility and stock availability. Stock visibility refers to the e-tailer's ability to see the stock electronically wherever it is in the system, whether this be in a warehouse, en-route to a customer, or being returned by a customer. With so much trade being international by nature, it is difficult to maintain stock visibility in the system as a whole. Stock availability is linked to its visibility and refers to the ability of the e-tailer to know how much stock is available in the system as a whole—that is, having a picture of their *virtual* stock. Thus, if a customer A in location x wants to order a particular item, the e-tailer needs to know that even if it is not in stock at their warehouse, there is a customer B in location y who is in the process of returning that particular item and that it could be available for customer A in say, 2 days. Unfortunately, the ICT (information and communications technology) required to have full stock visibility and availability is very complex and expensive and so very few e-tailers have it.

E-tailers should take returns into account when ordering stock. For instance, if they know that 30% of their products sold are likely to be returned, they should order 25%–30% fewer products to start with. That is, returns should be taken into account in their inventory management systems. However, this does not always occur. As stated above, the timing and condition of returns is often unknown to the e-tailer, so there is little stock visibility—making it difficult to operate accurate inventory management systems which should take into account the overall availability of a particular SKU (stock keeping unit).

Environmental Issues

The increase in cross-border trade has also impacted on reverse logistics trends. Although not always the case, returns are frequently sent back to the country from which the products originated; so if a British customer receives a product from Germany, for example, the product may also be returned to Germany. This is not always the case, as some e-tailers have taken the step of opening a “returns” center in some countries, particularly those in which the market for their products is quite large.

For mixed retailers, that is, those with both an online and a physical store presence, the potential exists for customers to return unwanted goods to the physical store. Once an item is returned to the store, it usually stays at the store for resale, thereby reducing the whole reverse logistics process. Many companies, even the largest ones, however, have not yet developed their computer software sufficiently to be able to cope with this and to enable them to deal with customer refunds for goods bought through a different channel. Currently, the omni-channel possibilities have not yet been extended to returns for many companies. This is an area where a great deal more work needs to be done.

Because of the scale of the returns problem, specialist reverse logistics companies have started to appear. Such companies, such as Clipper and ReBound logistics, not only deal with the processing of returns for other companies, but also specialize in providing intelligent digital algorithms to reduce a company's returns in the first place (for a review of this issue, see [Mangiaracina et al., 2015](#)).

Capturing Value

When products are returned by customers, companies will seek to maximize the value they can receive from these goods. Where possible, goods will be re-sold as new with little or no loss of value. This will not be possible for all items however. Some will be damaged; some will be counted as “old stock” and some will be past their sell-by date. There is a so-called hierarchy of reverse logistics. The precise hierarchy varies slightly between actors but, in general, from best option to worst option, it will include the following: Resell, repair, recondition, refurbish, remanufacture, cannibalize, recycle, and dispose. This hierarchy nowadays might also contain words such as “re-purpose” or “up-cycle.” The aim is to contribute to the circular economy with minimal waste and maximum profitability. Some items might be sold in end-of-season sales, in outlet centers, discount stores or secondary shops (either online, offline, or both) and some will be donated to charity. There have been horror stories about some e-tailers burning returned items, particularly in the case of “luxury brands” which do not wish to reduce a product's exclusivity by selling it in a secondary market, but this action adds little to profitability, is unpopular with the general public and is unlikely to persist in the long run.

The reverse logistics of certain products can be covered by legislation. In Europe, for instance, the Waste Electrical and Electronic Equipment Directive (the WEEE Directive, or EU Directive 2012/19/EU) was introduced in 2003 and has had several subsequent amendments, covers all electrical and electronic goods such as fridges, computers, toasters, lighting, cookers, etc. The Directive covers the collection, treatment, and recycling of all these goods and compels producers who sell their products in the EU to deal with them according to legislation. The aim is to reduce the quantity of such waste, which is sent to landfill in order to reduce the environmental and health effects of some of their hazardous content.

Reverse logistics also includes dealing with packaging and other items necessary for the safe and secure delivery of items ordered online, including logistics handling units such as pallets, trolleys, and crates.

Digitalization

Key to efficient e-logistics is digitalization. In reverse logistics, digitalization can help in reducing the number of returns that are made to start with and can aid the efficiency of the returns process. Included in the former category are developments such as digital changing rooms and AI (Artificial Intelligence) which can improve the alignment between expectations and reality; social media which can alert e-tailers to problems with the products through instant feedback pages and can help in the customization and tailoring of products to specific customers or groups of customers, as well as providing peer review opportunities. The quicker an e-tailer knows that a product is being returned, the greater the value that can be captured from the return. Digital tools such as EDI (electronic data interchange) that speed up communications between different parts of the logistics process and RFID (radio frequency identification) which enables product to be tracked and traced through the supply chain, can aid in increasing the visibility of a product to an e-tailer. Problems with operationalization of digital systems and platforms however are many. The issue of integration of different digital systems both within the company and between the company and its logistics partners is a difficult one. Most companies cannot afford to have new, bespoke systems and so have to incorporate additional elements or modules into their existing systems. This action is invariably second best and causes considerable integration problems. Another problematic area is making a choice decision between the huge arrays of digital systems available on the market. Many companies can identify multiple data and information requirements needed to improve the efficiency of their logistics processes. Prioritizing these requirements is difficult and trading off benefits against costs poses additional problems. Introducing new forms of digitalization can cost millions of dollars and this money can be completely wasted, if the system is not appropriate for the company (for a review, see Pettit and Wang, 2016).

Future Developments in E-Tailing and Reverse Logistics

Advances in this field are rapid and diverse. What seems futuristic one day can become quite normal within a few months. There is a great deal of competition in e-tailing and this is driving future developments, as companies strive to gain a slice of the e-tail pie. Such developments include the relatively low-key possibilities that might come with unattended collection and delivery points such as lockers, through innovative post boxes that allow companies to access them to deliver items and pick up returns. In the middle of the spectrum are drones and delivery pods. At the other end of the spectrum, developments in Artificial Intelligence, block-chaining and digitalization generally will improve the efficiency of e-logistics in ways that are currently unimaginable. It could, however, be changes in customer behavior or in fields seemingly unlinked to logistics (such as has happened with the development of social media) that dictates future developments in e-tail logistics.

Green Routing

Freight distribution entails the movement of goods from their origin to destination for which freight vehicles provide the basic means of transportation. While the term vehicle may have a more general connotation to include those of different modes, for example, a barge in water transport or rail cars in railways, the term is especially understood to be relevant to land transportation, and the vehicles that are used therein, such as a truck, a lorry, or a van.

Distribution of freight has undesirable, yet inevitable, impacts on the environment, also known as externalities, most of which arise in the process of physically moving the goods (Forkenbrock, 1999). Vehicles emit greenhouse gases, such as carbon dioxide (CO₂) or nitrogen oxide, and pollute the air through the release of others, such as methane, and small particles of dust. Emissions and air pollution result in phenomena such as acidification, summer smog, and depletion of the ozone layer. Other impacts include noise and vibration that cause damage to buildings and are detrimental to human well-being, use of land and natural resources for building and maintaining the necessary infrastructure, and accidents that cause injuries and death.

Freight can either be transported in full truckloads when goods are to be sent directly from their origin to destination, or in less-than-truckload shipments. The latter is relevant when goods are to be delivered to several destinations by a single vehicle, and are consolidated at the point of origin and loaded onto a vehicle prior to it being dispatched. In this case, the vehicle departs from the point of origin, often called the depot, visits the destinations (also called customers) in successive order, and returns to the depot. The sequence of visits is called a route, which may also entail the pickup of goods, in addition to delivery. Planning the routes of such vehicles is the aim of the class of problems known as vehicle routing, the basic version of which entails finding the best sequence of customers for a vehicle to optimize a given objective. The problem arises at the operational level of decision-making, typically executed on a daily basis. The vehicle routing problems that arise in practice, however, are often compounded with additional complexities, including the planning of routes for a fleet of vehicles, either all identical or with varying features, and other practical restrictions such as the limits on the amount of commodity transported due to vehicle capacity, or the need to deliver the goods within time slots (or time windows) dictated by the customers. A solution to the basic vehicle routing problem is a sequence of customers to be visited, one for each vehicle, where each customer is visited only once. The objective itself is often the minimization of economic cost, which may be measured in terms of the total distance traversed, the total time spent, or a similar measure of performance.

A green routing of freight vehicles is of concern when the problem entails an explicit consideration of environmental impacts of the distribution itself, with an aim to reduce the externalities as much as possible (Piecyk et al., 2015). Incorporating a particular externality into the planning of vehicle routes requires, however, an explicit representation of the said externality in some quantified form, such as a mathematical function of the various parameters that govern the externality. This is necessary to be able to measure the environmental impact of a given routing plan. Not all externalities can easily be represented using a functional form, however. Accidents or vibration are difficult to quantify, for example. Others are more amenable to such a representation because they are better understood. Emissions is a primary example of such an externality, particularly that of CO₂, which is known to be proportional to the amount of fuel consumed by a vehicle. Although the amount of carbon content in the fuel varies, the average value used by the European Environment Agency, for example, is 3.169 kg of CO₂ per kilogram of fuel (Ntziachristos and Samaras, 2018). The amount of fuel consumed, in turn, is a function of the energy required to move the vehicle, which depends on factors such as vehicle

load, speed, acceleration, and engine efficiency, and can therefore be better approximated. This is one reason why green routing of freight vehicles is predominantly concerned with reducing carbon emissions, which will also be the focus of this paper.

Emission Models

Emission models quantify the amount of greenhouse gases released by freight vehicles, and can either be in the form of a simple estimation factor expressed per unit of transport activity, or represented using a more detailed algebraic expression that includes various vehicle- and environment-related parameters. From a planning perspective, these factors can be classified into three, namely, activity-based, macroscopic, and microscopic, as detailed later (Demir et al., 2014; Bektaş et al., 2019).

Activity-Based Models

Also known as emission factors, these models calculate the emissions from a transport activity, and come in two types. The first type is used when the total amount of energy used or the fuel consumed by the transport activity is known, in which case it is simply multiplied by an emissions factor (e.g., in grams per kWh). If the total amount of energy used is not available, then factor models provide pre-calculated rate emissions from a transport activity based on the type (including capacity) of vehicle used, typically expressed in amount of carbon emitted per vehicle kilometer. The typical emission factors reported by the European Environment Agency, for example, range from 25.5 g of CO₂ per kilometer for a light commercial vehicle using conventional engine technology to 1.3 g of CO₂ per kilometer for the same vehicle using a Euro VI standard technology (Ntziachristos and Samaras, 2018).

Macroscopic Models

Macroscopic models are used for wide-area emissions assessment, where emission rates are measured for a given trip characterized by the type of vehicle used and the average speed v at which the vehicle travels. One of such models is described in the Air Pollutant Emission Inventory Guidebook by the European Commission (Ntziachristos and Samaras, 2018) that is an EU standard used to calculate vehicle emissions. The model is of the form $E(v) = b(a_1v^2 + a_2v + a_3 + a_4/v)/(a_5v^2 + a_6v + a_7)$, where $a_1 - a_7$ are parameters that are predefined on the basis of the fuel, class of vehicle, and engine technology used, and b is a correction factor applied, if necessary, to account for different types of road (i.e., urban, rural, and highway). The function $E(v)$ computes the hot emissions expressed in terms of grams per kilometer for a given average speed v . Figs. 1 and 2 show the resulting emissions produced using the data described by Ntziachristos and Samaras (2018) for light and heavy goods vehicles, respectively, that use different engine technologies.

Figure 1 CO₂ emissions calculated with the average speed model using the data described by Ntziachristos and Samaras (2018) for diesel light goods vehicles (maximum weight not exceeding 3.5 tons) and for different engine technologies.

Figure 2 CO₂ emissions calculated with the average speed model using the data described by Ntziachristos and Samaras (2018) for diesel heavy goods vehicles (maximum weight between 3.5 and 7.5 tons) and for different engine technologies.

Microscopic Models

Microscopic models provide for a much finer way to estimate emissions from a vehicle in an instantaneous manner (e.g., on a second-by-second basis). These models involve highly detailed expressions derived from mechanical physics of automobile engines (Ross, 1997) to calculate the tractive power required by the engine to move the vehicle over a given length of road. They also incorporate other demands for power including accessories (such as air conditioning). The tractive power itself is a function of a number of parameters that can broadly be classified into two, the first of which includes those that relate to the vehicle, such as vehicle mass (including empty weight and any load carried), instantaneous speed and acceleration, and the frontal surface area. The second class includes environment-related parameters such as road gradient, rolling resistance, drag, gravitational force, and air density. Assuming that all parameters, except for vehicle mass w and speed v , remain constant, a simplified form of a microscopic model to calculate the energy requirement $F(w, v)$ (in kWh) for the engine to traverse a road segment of length d can be expressed as follows:

$$F(w, v) = g(w \cdot d) + h(v^2 \cdot d), \quad (1)$$

where g and h are constants that can be calculated using the vehicle- and environment-related parameters. In calculating the total energy requirement, one would also have to factor in engine efficiency, which can then be converted into total fuel consumption by taking engine-specific parameters into account (Barth et al., 2005).

Planning for Green Routes

Vehicle routing problems are generally represented by optimization models, where the latter are solved using mathematical programming techniques. Green vehicle routing entails incorporating one or more externalities into the planning, which can be done by embedding the functions that represent the externalities into the corresponding optimization model. In the case of emissions, this can be done by adopting a particular emissions model and treating it as a minimizing objective function, or as a component thereof (Figliozzi, 2010; Qian and Eglese, 2016). The way in which the emissions model is incorporated into the optimization depends on the variables that can be controlled along a route, which in turn gives rise to several types of green vehicle routing problems, some of which are described as follows:

1. Fleet composition entails choosing, from a given set of vehicles with varying characteristics, such as capacity and weight, those to be dispatched, and the route that each vehicle is to follow. Fleet composition is particularly relevant to green vehicle routing as

the choice of vehicles will impact on emissions, which is due to the way in which vehicle-specific parameters affect fuel consumption. The type of vehicle used and the route chosen are interdependent decisions that should be made jointly (Koç et al., 2014).

2. Route optimization forms the main set of decisions to be made in the standard vehicle routing problem, which is also the case in green vehicle routing. One difference between the two problems is the need to factor in environment-related parameters into the planning models which are known to affect fuel consumption and emissions, such as road gradient and drag. Another difference arises due to the change of vehicle load from one delivery location to the next on a given route. As load affects fuel consumption, it would need to be considered jointly with the distance traversed. This combined effect in green routing is sometimes modeled by a function where the distance between successive delivery locations is weighted by the load carried over that distance.
3. If the traffic conditions allow for the (average) vehicle speed to be set freely, within legal limits, and implemented accordingly, then speed selection arises as another set of decisions that can be made to reduce emissions. If there are no time window restrictions present in the problem, then the choice of speeds is trivial. In this case, slowing vehicles down to their optimal speed at which fuel consumption is minimized can reduce emissions (McKinnon, 2016). Where there are time window restrictions, however, then speed choice becomes a nontrivial problem, especially given that speeds are inherently linked to route feasibility with respect to time. In this case, problems of route and speed selection need to be solved jointly (Bektaş and Laporte, 2011). Given a fixed route, speed selection gives rise to what is known as the speed optimization problem, which entails computing the average speed to be used when traveling between successive customers in order to minimize the resulting emissions (Kramer et al., 2015).
4. Acceleration is one micro-level factor that affects fuel consumption and emissions, and is inherently linked to speed choice on a given road segment. Choosing the speed and acceleration profile of a vehicle on a given road gives rise to an optimal control problem to maximize fuel economy (Hooker et al., 1983).

Generic Formulations

This section presents formulations to help conceptualize some of the problems described in the previous section. For simplicity, the models will assume the use of a homogeneous fleet of vehicles. Consequently, decisions concerning the selection of the number and type of vehicles will not be part of the decision problems described later, but models involving fleet composition decisions can be written in a similar fashion.

Route Optimization

The standard vehicle routing problem can be modeled on a graph described by a node set C of customers, with node 0 as the depot, and a set of arcs in between (possibly, but not necessarily, all) pairs of customers. The set R includes all routes that are feasible with respect to the problem restrictions, such as those on vehicle capacity and time. A constant cost c_r is defined for each route $r \in R$, which may be the total distance on the route, the total time to traverse the route, or a linear function of either.

The problem can be formulated using a binary variable x_r that is equal to 1 if route $r \in R$ is chosen, and is equal to 0 otherwise, and a binary parameter ξ_{ir} that equals 1 if the customer $i \in C$ is included in the route r , and 0 otherwise. Using this notation, one possible formulation for the standard vehicle routing problem can be described as follows.

$$\text{Minimize } \sum_{r \in R} c_r x_r \quad (2)$$

subject to

$$\sum_{r \in R} \xi_{ir} x_r = 1 \quad i \in C \quad (3)$$

$$x_r \in \{0, 1\} \quad r \in R, \quad (4)$$

which will select a number of routes from within the set R so as to minimize the total overall cost, and in such a way that each customer is included in only one route as dictated by constraints (3).

If one is to use activity-based models, then the cost c_r of a route $r \in R$ can simply be changed to reflect the unit energy or fuel consumption, or emissions, such as $\hat{c}_r = u \cdot d_r$, where u is the rate of emissions per vehicle per distance traveled (e.g., kilometers), and where d_r is the length of route r (e.g., in kilometers). However, the use of such a model assumes that parameters that affect fuel consumption or emissions along a given route, such as vehicle load or speed, remain constant, which may not necessarily hold in practice. This is particularly the case when a vehicle makes several deliveries on a given route, which means that the load carried on the vehicle will change from one stop to another.

Route and Speed Optimization

If the intention is to plan for vehicle routes at a more detailed level by controlling variables such as load and speed, then the use of microscopic models that incorporate such variables as input in calculating emissions may allow for a finer level of detail in the modeling. In vehicle routing, the load of the vehicle changes from one customer to another as deliveries are made along a route. Vehicle speed, on the other hand, is continuous and can change instantaneously along an arc. For planning purposes, however, speed could be expressed as the set $S = \{s_1, s_2, \dots\}$ of discretized average speeds. For a given route characterized by the sequence of customers visited, let $V_r \subseteq S$ be the set of speed vectors for a given route $r \in R$, where each vector $v_r \in V_r$ represents the feasible speeds that can be assigned to each pair of successive customers on the route. Under time window constraints, not all discretized speeds may be achievable. In this case, the planning involves solving a route and speed optimization problem, which concerns jointly determining the routes and the speeds on each leg of each route. One formulation for this problem, shown later, uses a binary variable x_{rv_r} equal to 1 if a route $r \in R$ is selected that uses the speed vector v_r , and equal to 0 otherwise.

$$\text{Minimize} \quad \sum_{r \in R} \sum_{v_r \in V_r} \bar{F}_r(w, v_r) x_{rv_r} \quad (5)$$

subject to

$$\sum_{r \in R} \sum_{v_r \in V_r} \xi_{ir} x_{rv_r} = 1 \quad i \in C \quad (6)$$

$$\sum_{v_r \in V_r} x_{rv_r} = 1 \quad r \in R \quad (7)$$

$$x_{rv_r} \in \{0, 1\} \quad r \in R, v_r \in V_r, \quad (8)$$

where constraints (6) choose one route for each customer and constraints (7) ensure the selection of one speed vector for each route. In the objective function, $\bar{F}_r(w, v) = \delta \cdot F_r(w, v)$ the total amount of emissions on route r , derived using (1) and δ is a conversion factor from energy to emissions.

In most instances, fuel consumption and total time spent en route are conflicting objectives, as the optimal speed that minimizes fuel consumption or emissions is not always the fastest possible speed (Figs. 1 and 2). The latter can be expressed in terms of value of time or money paid to the drivers. If τ_r denotes the time spent on each route, minimizing both objectives would give rise to the following bi-objective formulation:

$$\text{Minimize} \quad \sum_{r \in R} \sum_{v_r \in V_r} F_r(w, v_r) x_{rv_r} \quad (9)$$

$$\text{Minimize} \quad \sum_{r \in R} \sum_{v_r \in V_r} \tau_r x_{rv_r} \quad (10)$$

subject to (6)–(8). It is possible that the two objectives can be converted into a single monetary objective by using unit fuel cost (e.g., cost per liter) for the former and driver wages (e.g., cost per hour) for the latter.

Speed Optimization

Speed optimization is a scheduling problem that determines the arrival times to each of the k customers visited in a fixed sequence $(0, 1, \dots, k)$ by adjusting the speed $v_{i,i+1}$ in between every successive pair $(i, i+1)$ of locations, where $0 \leq i \leq k-1$, in order to optimize a given function. The problem is nontrivial when each customer $i = 1, \dots, k$ requires a visit within a prescribed time interval denoted by $[a_i, b_i]$. In addition, speeds must be chosen within an interval $[v_l, v_u]$, dictated by legal restrictions and traffic conditions. Within green routing, the objective would be to minimize a fuel consumption function such as (1), specified for each leg $(i, i+1)$ of the route as $F_{i,i+1}(w, v)$. A model for the speed optimization problem is given as follows.

$$\text{Minimize} \quad \sum_{i=0}^{k-1} F_{i,i+1}(w, v) \quad (11)$$

subject to

$$t_{i+1} - t_i - d_{i,i+1}/v_{i,i+1} \geq 0 \quad i = 0, \dots, k-1 \quad (12)$$

$$a_i \leq t_i \leq b_i \quad i = 1, \dots, k \quad (13)$$

$$v_l \leq v_{i,i+1} \leq v_u \quad i = 1, \dots, k \quad (14)$$

The variables t_i that appear in the formulation indicate the service start time for each customer $i = 1, \dots, k$, calculated using constraints (12), which are constrained to be within the required service by (13). Constraints (14) simply ensure that the chosen speeds are within the allowable limits.

Optimal Control

This planning problem pertains to finding an optimal driving profile for a vehicle characterized by the speed $v(t)$ and acceleration $a(t)$ of the vehicle, expressed as a function of time t , as it traverses a road segment of a given length d over a duration of T time units. The vehicle is assumed to have an initial speed equal to v_0 and the road has a gradient equal to $\theta(l(t))$. The length $l(t)$ is the distance traversed by the vehicle at time t from the starting point. A formulation for the optimal control problem is given as follows.

$$\text{Minimize}_{v,T} \int_0^T f(v(t), a(t)) dt \quad (15)$$

subject to:

$$\dot{l}(t) = v(t) \quad (16)$$

$$a(t) = \dot{v}(t) + g \sin \theta(l(t)) \quad (17)$$

$$a(t) \leq \bar{a}(v(t)) \quad (18)$$

$$v(0) = v_0 \quad (19)$$

$$s(0) = 0 \quad (20)$$

$$s(T) = d. \quad (21)$$

The expression $f(v(t), a(t))$ that appears in (15) is the rate of fuel consumption that is a function of both speed and acceleration. The acceleration itself is subject to a maximum value of $\bar{a}(v(t))$.

Outlook

Various algorithmic techniques have been proposed to solve the types of mathematical models of green routing problems described earlier, ranging from exact techniques to heuristics. Applications have been reported on practically relevant problems that differ with respect to the model that is used to calculate emissions, the variables used in the planning (e.g., load and speed), practical restrictions, type of environment (long vs. short-haul, urban vs. intercity), and so on. While the reported results are case-specific, they collectively indicate that savings in emissions are possible by incorporating a finer level of detail in the route planning, which can be significant in some cases. In some cases, the savings in emissions can be reaped without a significant compromise in operational cost, suggesting that win-win solutions may well be possible in green vehicle routing in which environmental and economic criteria are simultaneously optimized.

Introduction

In a firm's logistics activity, the mode choice decision process would be considered only at one stage by shippers, who must make choices on "How" to move the consignments taking into account destination and shipment sizes. However, it is at this stage the interests of three major institutions associated with freight transport (i.e., the government, the carrier, and the shipper) mainly coincide.

Due to growing concerns about urban congestion, environmental impact, public health, and safety considerations, freight transportation has increasingly become of vital importance in logistics decision making in particular, and in the industrial process in general. In order to manage the issues, firms consolidate their freight flows and outsource the transport and logistics activities. Among the shippers and logistics providers, the effective use of varying transport modes is not yet widely accepted as an alternative when addressing transport problems. Although the choice of an appropriate transportation mode is vital for the logistics process in a global industrial process, shippers, and firms feel constrained by the logistics trade-off, such as the trade-off between the level of inventory versus the level of customer service.

Market globalization and the development of service economies have increased the demand for reliable, flexible, timely, and cost-effective freight services to shippers. The Organisation for Economic Cooperation and Development (OECD) predicts that global freight transport demand (in ton-km) is expected to grow by about 294% between 2015 and 2050 (OECD/ITF, 2017). The OECD expects the steady growth of freight movements to continue and increase by almost 100% by 2040. Concurrently, the modal share of road transport has increased significantly and is expected to increase further in the coming years. In addition, with rising fuel prices and growing awareness about the challenge of global climate change, innovative policies and technologies to reduce the negative impacts of the dependency on road transport are being introduced. Despite the dynamic nature of the business environment, few studies have attempted to systematically establish a relationship between the shipper's mode choice perception and their logistics characteristics in the freight transportation market.

Freight Mode Choice Decision Factors

The allocation of freight among transport modes, often known as mode choice, is one of the most controversial topics in the field of transport logistics. This is because many mode choice decisions are not always based upon a full and rational appraisal of options available, and commercial decisions generally do not consider the total cost of each mode or modal service, especially external costs related to safety and environmental impacts.

The choice of transport mode has a direct impact on the efficiency of logistics channels and systems. Each transport mode possesses different characteristics and different strengths and weaknesses. Depending on the mode chosen, the overall performance of the logistics system will be affected. Transport decision-makers choose the transport mode within a logistics system and depending on the decision maker's requirements, unimodal, multimodal, or integrated transport logistics will be utilized. It is important to recognize the impact of the decision maker's perceptions on the selection decision.

The perceptual approach assumes that the explanatory variables influencing transport mode choice are determined by the transport user's perception of subjective quality measurements, rather than by objective measurements. This approach treats transport as a product purchased like any other product. A range of empirical studies performed from the 1970s to the 2000s shows that freight shippers have varying perceptions of alternative transportation modes such as road, rail, and intermodal. Research

indicated that shippers generally consider freight logistics characteristics and modal characteristics as important in the mode choice decision process. More recent research shows that logistics attributes such as frequency of shipments and flexibility of mode use, are important factors, as the globalization of business increases the need to have effective and efficient transport.

The shipper's freight logistics characteristics, such as the attributes of the shipper, the attributes of the commodities to be transported, and the spatial attributes of shipments such as the origin and destination of shipments and location of warehouses or distribution centers, strongly influence the choice of mode. These can be categorized as follows:

- the operational characteristics of the firms (i.e., business type, size of the firm, and type of transport fleets);
- the physical characteristics of shipments (i.e., type and value of goods, size of shipment, packaging of shipment, and frequency of shipment);
- information about the linkages and itinerary of the shipments (i.e., location of customers, location of warehouses, and distribution centers); and
- the choice between alternative carriers.

The shipper's decision to use a particular transportation mode is generally based on several factors. Several studies have been conducted to identify the specific service attributes often considered important in the shipper decision process. The decision-maker's own perception is a significant input to the decision-making process in mode selection. Also, the overall perception is typically driven largely by at least six perception factors, such as transport rates (including cost and charges), transport time (including transit time), transport reliability (i.e., on-time delivery), loss and damage to goods, modal availability (i.e., service frequency), and the value of transport service provided by carriers or transport service providers.

The rankings of factors differed between different studies of carrier selection in freight mode choice studies from the 1970s to the 2000s. The importance of freight rates increased in the 1980s, but reliability was always ranked on top. Transit time was the second most important factor in the 1970–80, but has steadily declined the importance in the 2000s. In some market segments, though, freight rates were more important than all other service factors. According to the study, the US shippers' overall perceptions are more affected by timeliness and availability than rates, which is often the last criterion for selecting a transport service provider. More recent studies have shown that shippers value service and reliability higher than cost or any other factors.

Freight Transport Decision-Makers

In freight transport, shipping decision-makers are generally classified into three categories: own-mode shippers, carriers, and shipping brokers. Own-mode shippers (or consignors) are shippers that deliver shipments with their own transport. Carriers, also called for-hire carriers, are the agents (e.g., trucking company, railway company) that move the shipment from the shipper to the consignee or customer, on behalf of the owners of the goods.

In the for-hire freight transport market, the prices of freight services are usually difficult for an analyst to get, as both transport firms and their clients try to keep such data confidential. [Ortuzar and Willumsen \(2011\)](#) classify what are thought to be the important factors affecting charges or cost implications:

- the length of the contract;
- the volume of shipments;
- the availability of alternative modal facilities;
- the availability of own vehicle; and
- the hierarchy of the transport system and network.

Freight agents or brokers act as intermediaries and handle the booking of the trucking company or other modes of transport for shippers without their own transport. These categories are not necessarily mutually exclusive. For example, it is possible for third-party logistics (3PL) companies to own their own vehicles and deliver a shipper's goods. 3PL providers typically specialize in the integrated operation of warehousing and transportation services. This can be scaled and customized to meet a customer's needs based on market conditions and the demands and delivery service requirements for the customer's products and materials. These days, most 3PL companies handle all aspects of transportation including warehousing, intermodal transfer, rail, container, cold storage, and air freight transport.

Road Transport: Owned-Fleet or For-Hire Vehicles

The firm or shipper has a choice whether a carrier will be contracted to move goods or the firm will own and use its own trucks. An owned-road fleet, also called private carriers (the United States), private trucking (Canada), or own account carriers (EU), are operated by firms whose principal occupation is not trucking, but who transport their own goods. For-hire (the United States and Canada) or hire-or-reward (EU) operations are transport services provided by transport service providers.

Owned-fleet trucking accounts for a significant amount of the trucking industry's activity in the United States and Canada. According to the study commissioned by the American Trucking Association in 2006, it has been estimated that private carriers

handled about 48% of the freight volume by tons hauled by all trucks in the United States, while owned-fleet trucking is dominated by a large number of small fleets operating in and around urban areas in Canada, where it holds an 85% share of the urban trucking market (Arthurs, 2006). The Private Motor Truck Council in Canada indicates that for urban goods movements, owned-fleets account for 85% of the trips within 160 km distance, for 25% of the trips within 500 km distance and for 10% of the trips of 500–1000 km.

Nowadays, not many firms set up their own private transportation operation, unless they have unique service requirements that cannot be met by for-hire carriers. The disadvantage of having one's own fleet is the investment in equipment, facilities, and people to operate and manage it. According to the Road Transport Vademecum (European Commission, 2011), about one-sixth of ton-km of road freight in the EU is transported by owned-fleet. In 2010, the share of owned-fleets was only 15.2%, compared with 15.8% in 2008 and 16.9% in 2009. Owned-fleet transport is relatively strong in Germany where it has a share of slightly more than 20% of total activity.

In other EU member states, such as France, the United Kingdom, Finland, and Sweden, the proportion of goods moved by for-hire carriers rose during the last ten years. The Vademecum also found that the proportion of empty runs is higher for owned-fleet transport than for for-hire transport. In 2010, it was 30.6% for owned-fleets but just 21.4% for for-hire carriers. Reflecting the situation with empty runs, for-hire transport is more efficient than owned-fleet transport in terms of the average load factor, with 8.5 ton-km for owned-fleets and 14.5 ton-km for for-hire carriers. The EU study reveals that around three-quarters of goods are transported 150 km or less. This is similar to the situation in the United States and Canada.

Modeling Freight Demand and Mode Choice

In freight demand studies, the discussion of shipper behavior modeling is quite extensive and approached in many different ways. Regan and Garrido (2002) classified the mode choice research on shipper behavior models as:

- the private versus for-hire carrier selection process;
- shipper-carrier relationships and carrier selection criteria, including the development of shipper-carrier alliances; and
- 3PL service provider.

Freight demand models have been developed since the 1960s. The published studies fall into three main categories: econometric models, spatial price equilibrium models, and network equilibrium models. Based on the nature of the data used for estimation, Winston (1993) also classified freight demand models as either aggregate or disaggregate models.

Aggregate models are defined as models that use an aggregate share of freight mode as the basic unit of observation for the model at a specified geographical level. The majority of freight models applied in practice have been of the aggregate kind, which applications follow the four-stage model as used in the personal transport model. In comparison to aggregate demand models, disaggregate models reflect in more detail the behavioral realities of freight transport decision-making, including the question of which “actor” (i.e., the owner of goods, carriers, or brokers) actually chooses the mode of transport. Disaggregate demand models are based on theories of individual behavior. Therefore, disaggregate demand models are probabilistic and attempt to explain individual behavior using individual data. The explanatory variables included in such models can have explicitly estimated coefficients. In principle, the utility function allows any number and specification of explanatory variables, as opposed to the case of the generalized cost function in conventional models, which is generally limited to only a few fixed parameters, such as the monetary and nonmonetary costs of a journey.

Disaggregate demand models can be classified into two classes: the so-called “inventory” and “behavioral” models. Inventory-based models analyze freight demand from the perspective of an inventory manager who deals with several production decisions, while the behavioral models deal with only one decision, the choice of mode.

In disaggregate freight mode choice models; mode choice is modeled at the level of individual shipments. The models use data from surveys of shippers, commodity surveys and so on. A combination of revealed preference (RP) and stated preference (SP) data have been widely used in the field of travel behavior studies. In general, the RP data captures individuals' actual choice responses to actual alternatives in current options. Using SP data allows the impact of policy variables on mode choice to be incorporated in the modeling. In particular, the relative importance of variables other than cost and time (e.g., reliability) can be identified. The models tend to be multinomial or nested logistic regression models, which can be based on the economic theory of individual utility maximization. The theory and method of discrete choice models were developed by Daniel McFadden, who won the Nobel Prize for economics. Kenneth Train extended the framework for modeling choice behavior by introducing simulation methods and software. Multinomial logit (MNL) and mixed logit (ML) are probably the most widely used methods for predicting freight mode choice.

During the last two decades, the development of discrete choice models has mainly been concerned with modeling the heterogeneity of the unobserved effects at the individual level. This is referred to as scale heterogeneity. The ML models account for scale heterogeneity in individual preference and error variance, but they cannot be directly explained by the inclusion of socio-demographic or behavioral variables through the use of random parameters. To control for scale heterogeneity, the generalized MNL model and generalized ML model have been introduced recently as an extension to the MNL models.

Behavioral Demand Model

The behavioral models attempt to explain freight transport demand as a process of utility maximization with respect to the choice of mode. For generating discrete choice models, “random utility theory” assumed that a freight shipper has possible multi-attribute transport modes from which to choose. The shipper will choose the mode with the largest associated utility among the available modes. Therefore, the mode choice probabilities depend on the random utility differences and their distribution (e.g., the receiver’s attitude toward risk), and the expected value of the unobserved modal, commodity and firm attributes, as well as measurement error.

Winston (1981) developed a model of freight demand based on the random utility model and used disaggregate data for a broad set of markets. In practice, the choice of mode may be made by either the shipping or receiving firm. When a firm is paying the transportation charges, the regional physical distribution or logistics manager at a shipping point generally has control over the manner of shipping. It is often the case, however, that purchase orders issued by the receiving firm include, among other things, the choice of mode as requested by the receiver’s logistics department. In this case, the receiving firm makes the mode choice, and hence, pays the transportation costs. Where the shipping firm makes the mode choice, it pays the transportation costs.

Different transportation modes are distinguished by their service attributes. The transportation cost is affected by such attributes as the availability of equipment, travel time, price, the flexibility of the service, reliability, insurance cost, loading facilities, etc. In addition, the component of the level of service of each mode introduces risk (e.g., higher risk of damage to goods and low on-time reliability) into the shipper’s decision regarding mode and destination.

Inventory-Based Model

Inventory-based models are theoretical in nature. Such a demand model analyses the transport mode decision made by shippers and the total demand for transportation services. The shipping cost per unit, the mean shipping time, the variance of shipping time, and the in-transit cost are typically assumed to determine how a shipper chooses between modes. The inventory theory investigates the trade-off between attributes for firms maximizing profit. From the total profit equation, the optimal demand for transportation in the firm’s supply chain (i.e., the location of logistics facilities, level of inventory, and vehicle routing) can be calculated using nonlinear estimation techniques.

The optimal demand for transportation, explicitly defined as an annual tonnage shipped, is calculated using nonlinear estimation techniques. This approach contributes analytical power to the inventory-based theoretical model and enables estimation of what would happen to demand given a change in any of the attributes. However, the limitations of the approach include its inapplicability to situations involving examining anything more than mode choice.

Revealed Preference and Stated Preference Methods

To develop a choice model, it is necessary to have data on an individual’s or firm’s choice response and operational characteristics. Parameters of behavioral models could be estimated using both surveys of actual travel behavior in a real context and surveys of hypothetical travel behavior in nonexistent scenarios.

In general, the RP survey captures individuals’ actual choice responses to actual alternatives. This method assumes that the preference of respondents can be revealed by their choice behavior. The advantage of the RP survey is that it captures actual behavior, which gives high validity to capturing freight shippers’ actual mode choices and ranking of several predetermined attributes that may influence the choices. However, because data from revealed preferences considers only current options, RP surveys are constrained to making predictions only for observed options. RP surveys are also restricted in their use due to the difficulty in measuring when a higher number of alternatives exist, and there is a need to allow for collinearity of attributes, as they can be closely correlated in real life.

The SP survey uses a specially constructed questionnaire to elicit estimates of the willingness to pay (WTP) for or the willingness to accept (WTA) a particular choice. WTP is the maximum amount of money an individual is willing to give to receive a good or service. WTA is the minimum amount of money they would need to abandon a good or service.

Different SP methods are available under a wide variety of names, for including contingent valuation (CV), choice experiment (CE), conjoint, functional measurement, trade-off analysis, and the transfer price method. The best-known are the CV and CE methods. CV is a technique for the valuation of nonmarket resources and involves constructing and presenting hypothetical situations to the survey respondents. The term “CV” was originally used for a survey to estimate the economic value of a public good or service. The CV conveys three main elements: (1) information related to preferences is obtained using an SP survey, (2) the study’s purpose is placing an economic value on one or more goods, and (3) the good (s) being valued are public ones. A detailed description of a good or service, how it will be provided, and the method and frequency of payment, are usually highlighted in the CV questionnaire. Following this, questions are posed in order to infer a respondent’s WTP or WTA. CV questionnaires also generally contain additional questions to gain information on a respondent’s socioeconomic and demographic characteristics, their attitudes toward the goods, and the reasons behind their stated valuations. The key outcome of the analysis of the responses is an estimate of the average WTP across the sample of people surveyed. If the sample is representative of the target population, then this estimate can be expanded to obtain an estimate of the total value of the outcome or good.

The CE method focuses on a good's or service's attributes and their values. There are three essential elements to the CE method: (1) a respondent is asked to make a choice between two or more alternative hypothetical options (choice set), (2) the alternatives are described by its characteristics, also referred to as attributes, and (3) the attributes are specified by several levels depending upon the nature of these attributes. To develop valuation estimates, CE questionnaires present respondents with a series of alternative goods or services. The alternative descriptions are constructed by varying the levels of the attributes. Depending on the specific CE adopted, respondents are either then asked to rank, choose, or rate the descriptions presented.

The SP method is more flexible than the RP method and can avoid multicollinearity problems, such as similarities in attribute levels and the shared-relationships between attributes, because all the relevant information for making choices between alternatives is provided to the respondent. However, there has been debate regarding whether stated intentions reflect current conditions, as SP data does not always accurately predict overall market share. Despite this weakness, the SP approach is widely used for the valuation of nonmarket resources, such as environmental preservation or the impact of contamination; while those resources give people "utility," they do or may not have a market price and are not sold directly. In addition, SP studies are used to investigate respondents' preferences toward alternative (s) not yet available in the market (e.g., improvement of the public transport system or introducing a new service), or to investigate alternative (s) outside the current technological frontier.

Utility is a broad concept that may refer to a person's welfare, well-being, or happiness. For example, freight shippers or firms receive non-price benefits from choosing optimal transport modes to distribute goods, but the decision-making process would be difficult to value using a price-based model such as the RP method. The SP method is a good technique for estimating the non-price aspects.

Traditionally, RP data were commonly used in transport analysis for estimating ton-km transported by a given mode. However, in the last two decades, SP techniques have been gradually introduced in passenger transport demand analysis and, less frequently, in freight transport demand analysis. The advantages and disadvantages of the two techniques compensate for each other and can be used jointly.

Introduction

The value of time (VOT) is a critical aspect in decision-making in transportation. One of the key objectives of any transport investment is the reduction in travel times. Governments employ cost-benefit analysis (CBA) as a framework for a transparent evaluation of the economic and social effects of projects and to ensure that their actions and investments in transportation infrastructure use resources in the most efficient manner. The process of evaluating the benefits of particular transport infrastructure investments often requires assigning money values to factors that lack observable market prices. One of the most important of these factors is travel time, which has been the subject of research for decades, with significant advances both from a theoretical and empirical perspective.

The theoretical underpinnings of the VOT are inherently related to the economic theory of time allocation introduced in the 1960s (Becker, 1965). Based on the idea that time is a scarce resource, pioneering theories were formulated in the context of people—commuters—and framed around a utility maximization problem, subject to constraints on income and the minimum amount of time required by the various activities that individuals undertake.

In the case of freight transport, while the problem still remains a maximization problem, it is generally defined as a profit maximization problem, subject to constraints on costs of production and transportation. The main difficulty with freight transport is to identify the economic agent whose profit function needs to be maximized. While the decision about the transport mode and route may be made by a transport hauler, a freight forwarder or other transport operator, the benefits obtained from a reduction in transit times may be part of the profit function of the shipping firm, as well as of the firm or consumer that receives the goods.

In general, the VOT is defined as the monetary value that users are willing to pay—or to accept—for a reduction—or an increase—in travel times along a particular origin-destination pair. In this chapter, the specific characteristics of the VOT in freight transport are outlined, highlighting how the various methodologies have dealt with the idiosyncrasies of this key indicator in infrastructure-related CBA.

The monetary value of travel time in freight transport goes beyond the valuation of the willingness to pay for transit time savings. While this is indeed a key aspect to take into account, the final delivery time—total time since the customer places the order until he receives it—is determined not only by how fast goods are transported from origin to destination, but it is also determined by the reliability of these transit times and the frequency of the transport service. Monetary values for the reliability of travel times relate to reductions in travel time variability on a determined route. This time variability has been identified as a key determinant in the valuation of time in freight transport.

Overall, the relationship between transit time, reliability, and frequency becomes more relevant for transport modes with fixed schedules and comparatively lower levels of frequency, such as maritime and rail transport. This relationship is particularly important for multimodal transport chains typically characterized by having a more limited scope for transit time improvements. In modal switching initiatives, where governments are to make policy decisions about freight transport by road and the promotion of alternative modes to induce modal shift, the VOT should be assessed in conjunction with the value of reliability (VOR) and the value of frequency.

Estimating the Value of Time in Freight Transport: Key Challenges

The Decision Maker

Unlike passenger transport, where the decision maker is the traveler, there are multiple agents involved in the freight transport decision-making process, with no clearly identifiable pattern of responsibility and involvement by each decision maker in the

various logistics decisions. Agents involved in freight transport decision-making are normally aggregated into two groups: carriers and shippers. Carriers are those agents whose primary activity is directly related to the transportation of the goods. These agents are involved in the provision of transport services both directly—road haulers, shipping lines, rail operators, and air carriers—or indirectly—freight forwarders and logistics operators. Alternatively, shippers are those agents whose primary activity is related to the production and distribution of goods. Shippers can either be the shipping firm or the receiving firm, and the agreed International Commercial Terms or INCOTERMS ultimately determines this role. In some cases, shippers act both as shippers as well as carriers—own account shippers—carrying out their own transport operations.

The correct identification of the decision maker is one of the key challenges in modeling freight transport demand and, therefore, in estimating the VOT in freight transport. This is important from a data collection perspective as well as from a modeling perspective. First, it is crucial to ensure that the agent providing the information is the one responsible for the final decision under study. Here the difficulty is not limited to identifying the company responsible for the decision, but to identifying within that company, the person in charge of these decisions. From a modeling perspective, while the benefits obtained by carriers from transit time savings relate to savings in operational costs, such as labor costs, fuel, and vehicles, the benefits obtained by shippers relate to savings in the associated production or distribution process. This has motivated a distinction in the literature between two approaches for estimating values in freight transport: the factor-cost approach, which focuses on the transport cost component of the VOT, and the modeling approach, which centers on the cargo component of the VOT, with the sum of both representing the overall VOT (De Jong et al., 2014).

Under the factor cost approach, the debate focuses on the type of costs that should be included in the estimation process, which in turn depends on the time horizon of reference. In the short run, firms may have difficulties in taking full advantage of the benefits associated with transit time savings. However, in the long run, with a greater perception of the steady benefits from transit time savings, firms are likely to make a more effective use of resources that may result in a further cost reduction and therefore a higher VOT.

The modeling approach is the most widely used method in the estimation of the VOT in freight transport. Based on the implied time-cost trade-offs made by the decision maker, this method is based on the use of discrete choice models, where the VOT corresponds to the time-cost marginal rate of substitution. These models are in line with those used in passenger transport studies, but with added specific challenges specifically associated with the freight transport context, such as the greater heterogeneity in transport flows and difficulty in obtaining data.

Difficulty in Obtaining Data

The data collection process in freight transport studies can be arduous and expensive. At the aggregate level, where the basic unit of observation is the market share at the regional or national level, freight transport datasets are relatively scarce, lacking in detail and too broad to carry out any comprehensive demand side analysis. Therefore, there is often the need to complement these datasets with information from other secondary sources.

Most of the empirical applications that use the modeling approach require the collection of their own disaggregated data through surveys and questionnaires. In these cases, the basic unit of observation is the transport or logistics decision made by the decision maker. Two main approaches can be distinguished: the inventory approach (Baumol and Vinod, 1970), where the transport decision is integrated in the production decision-making process, and the behavioral approach, where the transport decision is based on a consumption decision based on maximizing utility (Winston, 1983). In any case, the data collection process in freight transport is generally more complex than in the case of passenger transport. This is mainly due to the reduced availability of firms willing to participate in the studies, as well as the greater reluctance to provide sensitive commercial information.

Under the behavioral approach and depending on the type of data used, studies can be classified into revealed preference studies—data from choices actually made by decision makers—and stated preference (SP) studies—data from choices based on hypothetical situations, with the latter being the most widely used in freight transport applications. In SP studies, the firm is asked to declare their choice under a hypothetical situation put forward by the researcher and, therefore, does not have to provide information about their actual behavior, which contributes to reducing the respondent's understandable reluctance to provide sensitive commercial information. However, the main challenge in SP studies is in ensuring that these hypothetical situations are perceived by the interviewee as realistic, as well as in avoiding lexicographic behaviors due to an inadequate design of the experiment, that is, negligible trade-offs between the levels of service of the attributes displayed. The high levels of heterogeneity of freight transport flows make the identification of the boundary values leading to changes between alternatives particularly complex. In this sense, the use of SP experiments pivoted around the reference alternative provided by the interviewee, and the definition of the variations in the levels of the attributes in relative terms allows the experiment to be adjusted to the particularities of the shipment. Moreover, recent methodological advances in the last decade have increased the efficiency of SP studies, that is, efficient designs (Rose et al., 2008), and have allowed these methods to partially offset the lower sample size often found in freight transport applications.

Heterogeneity

There is a considerable level of heterogeneity in freight transport flows. This is due to the physical characteristics of the goods transported and the transport chains involved, as well as to the logistics requirements of individual consignments. In contrast to

passenger transport, where the unit of reference is straightforward, the traveler, there is no single unit of reference in freight transport. With a wide range of units used—tonnes, shipments, TEUs, lorry, wagon, barge, etc.—the choice of the reference unit ultimately depends on the decision maker, the data availability, and the research objective. In any case, even with identical units of reference, results from different studies may not be directly comparable. The high level of heterogeneity that characterizes the goods transported means that if using the shipment as the reference unit, it may differ by size to a great extent from, for example, a shoebox to a grain barge. This also applies to some extent to the tonne, with great heterogeneity in terms of volumetric weight across goods.

Some of this heterogeneity can be captured by simply taking into account the mode of transport and type of cargo—bulk or unitized and, within the latter group, full container load (FCL) or less container load (LCL). For example, dry bulk shipments, which are unpacked and homogeneous, show certain specific characteristics from a logistics perspective—larger size and reduced unit value—and therefore, attributes, such as the cost of transport, become a key determinant of their relative competitiveness. This means that generalizing the various estimated transport attribute values, such as the VOT, may be more challenging. In the case of unitized cargo and in particular the transport chains associated with LCL, which imply additional loading/unloading operations, there are often significant differences in the relative competitiveness for the various transport modes, being the VOT per unit of product usually higher for smaller shipments—LCL—than for FCL. In any case and from a CBA perspective, while taking into account the distinction between FCL and LCL may result in higher accuracy in the valuation of time, this may be partially hampered by the relatively reduced quality of data from transport national statistics, which often ignore this distinction by equating shipments with trips.

There is a general consensus across the literature that freight transport valuation models should incorporate to some extent basic systematic sources of heterogeneity, such as those linked to the decision maker, the type of mode of transport, the format of cargo, size, distance, or the value of the goods. This is often carried out by either segmenting the sample or through interactions with other transport attributes, such as cost or transit time. The challenges associated with modeling freight transport demand—large heterogeneity, small population in relative terms and the difficulty in obtaining freight data—can make it difficult to simultaneously analyze all these factors, even though technological and methodological advances have made it possible to better address the issue of heterogeneity in the valuation of freight transport attributes.

From a methodological perspective, the use of mixed logit models (McFadden and Train, 2000)—where coefficients can be specified as random variables following a continuous distribution—and latent class models (Greene and Hensher, 2003)—where the population is split into Q latent classes with heterogeneous preferences across classes and homogeneous preferences within the class—have allowed for significant advances in the way heterogeneity is now dealt with in freight transport studies.

Advances are also being made in the way in which decision-making processes are incorporated into the models. In this sense, while model specifications with symmetrical preferences—implying equal willingness to pay (WtP) and willingness to accept (WtA) measures for variations in transit times—are more common in the case of freight transport, there is an increasing body of literature that introduce elements of prospect theory (Kahneman and Tversky, 1979) to assess if the loss aversion hypothesis holds in the case of freight transport. These empirical applications are focused on determining whether the impact of deterioration in the level of service is higher than an improvement in the same magnitude, which would imply that the WtA would be greater than the WtP for a particular level of service. This line of research is especially relevant in the context of reducing the environmental impact of transport systems as a policy objective. From this perspective, the development of more environmentally efficient transport chains might imply reconsidering the levels of service provided in terms of transit time, in which case the validation of the loss aversion hypothesis becomes crucial.

Until now, most of the empirical evidence available on this issue in the area of freight corroborates the loss aversion hypothesis (Masiero and Hensher, 2010; Masiero and Rose, 2013). In any case, differences in WtP and WtA will ultimately depend on the relative level of service provided across the various transport alternatives considered and the extent of the deterioration or improvement considered. In this sense, more research is needed to analyze the existence or not of diminishing sensitivity, as there is hardly any empirical evidence on this issue in the field of goods transport.

Noncompensatory behaviors are also being considered through the specification of piecewise linear functions (Swait, 2001). In these specifications, a penalty component linked to the magnitude of the cutoff violation is added to the traditional linear-in-the-parameters nonpenalized utility function, where low levels of service of one attribute can always be offset by high levels of service of other attributes. This makes it possible to obtain different VOTs, depending on whether the corresponding cutoff is disregarded. When cutoffs are imposed, the VOT is expected to be higher when cutoffs are breached. While the empirical evidence on the imposition of cutoffs in the evaluation of transit time is not unique, in the case of transit time reliability it is possible to identify a larger number of investigations showing that these cutoffs apply (Danielis and Marcucci, 2007; Feo-Valero et al., 2016). Indeed, in some of those cases, the willingness to pay for improvements in the reliability within the “acceptable level of service” is zero. This result has significant implications in terms of the valuation of the benefits derived from specific actions.

Heterogeneity is not such a major challenge in valuation studies under the factor cost approach. The unit of reference is the unit of transport and the impact of variations in transit time over the operating cost do not usually depend on the size and the type of cargo. Under the factor cost approach, the difficulty comes from the conversion to a single unit of reference of the transport and cargo components of the VOT. Moreover, since empty trips may represent a significant proportion of the overall trips, a correction factor should be applied to the good component of the VOT when calculating total cost benefits linked to a specific transport project. Here again, accurate and up-to-date statistics on the proportion of empty trips would be needed.

Value of Freight Transport Reliability

The benefits from reductions in travel time variability were not taken into account in the valuation of travel time in freight transport until recent times. Measuring these benefits is important, as well as including them in the CBA of transport investment projects. From the shippers' perspective, these benefits may allow them to cut down on inventory costs and develop just-in-time strategies. From the carriers' perspective, benefits from reductions in travel time variability may result in greater optimization of their resources through more efficient planning. With the recent developments in production and distribution processes based on fast and reliable transport chains, minimizing vulnerability and the risk of disruption from unexpected delays have become more important. This has motivated an increasing interest in the measurement of the VOR in freight transport.

Most of the empirical studies regarding the value of freight time have historically focused on the analysis of transit time, with less empirical evidence on the role that delays had on the logistics decision-making process and the WtP for improvements in reliability. One of the main reasons for this limited empirical evidence is the difficulty in defining and measuring reliability. While other typical freight transport attributes, such as cost and frequency, are generally perceived by the decision maker as static for a given shipment, the key aspect to consider by the decision maker in the case of reliability is their experience over multiple shipments, which requires a greater level of mental effort (Tseng et al., 2009).

In freight transportation, reliability in the terms of delivery refers to the extent to which transit times for particular shipments correspond with the transit times initially agreed and expected by the decision maker. In general, reliability refers to the level of unexpected variability in travel times. There is no single method to measure this variability, which implies that a range of different reference units can be used. Therefore, it becomes increasingly hard to make comparisons across estimates from different empirical studies.

One of the most widely used methodologies to measure reliability in the terms of delivery is the percentage of shipments arriving within the scheduled time or alternatively, the percentage of shipments suffering significant delays. This is often completed with additional information on the average extent of the delays when these actually take place. Reliability can also be measured by calculating either the variance or the standard deviation with respect to the agreed transit time along the logistics chain under study. However, the need for the decision maker to assess a relatively complex concept, such as the variance, has motivated that recent studies substitute this variable by a range of possible transit times with an equal chance of occurring.

From the shipper's perspective, an additional aspect to consider is the impact of reliability on the preferred departure and arrival times (Fowkes, 2007). Taking into account these issues leads to the discussion between nonscheduled and scheduled shipments, depending on how important is the timing of the shipment for the decision maker. Under the scheduled-approach timing preferences are explicitly introduced in the model, usually through the magnitude of early and late schedule delays. The importance attached to the timing is determined by the production strategy adopted by the shipper/receiver, the type of transport chain—unimodal or multimodal—and the level of service in terms of frequency. While the importance of departure and arrival times for full truck loads may be relatively low, as the transport provider can adapt to the loading time window set by the shipper, it becomes critical in the case of multimodal transport chains where the main transport mode—maritime, IWT, rail, or air—displays relatively low levels of frequency and fixed schedules. In this sense, there are only a few studies that specifically analyze if the relative value of delays is affected by the point at which the delays take place along the door-to-door transport chain, by taking into account the interrelation between the different nodes and agents involved.

The reliability ratio (RR), defined as the ratio between the VOR and the VOT, is a useful indicator in empirical studies that include both estimates. Most studies have reported RRs greater than one, which implies that there is a relatively higher weight given to reliability relative to transit time (Shams et al. 2017). This suggests that while transit times matter in the case of freight transport, it is the reduction in the variability in transit times that matters the most to decision makers.

Conclusions and the Future of the VOT in Freight Transport

One of the key aspects of the evaluation of any transport project involves the monetary valuation of travel time. The intrinsic characteristics of freight transport make the estimation of the value of freight travel time somehow more challenging than the corresponding value for passenger transport. These challenges involve the identification of the decision maker—carriers or shippers—and the heterogeneity of freight transport flows—transported goods, transport chains, units of reference—as well as an additional difficulty in data collection due to the commercial nature of the activities under study.

The high level of casuistry inherent in logistic flows makes it very complicated to provide a unique VOT reference value. Thus the relative weight given to time in a short distance shipment will probably have little to do with that of an interoceanic shipment whose estimated transit time is more than two weeks. In the latter case, it is likely that the relevant aspect for the decision maker is the reliability and frequency of service, rather than the transit time. In fact, the latest restructuring movements of liner shipping services undertaken by some of the major shipping lines are partially aimed at improving the reliability of their schedules. Special mention should also be paid to the estimation of the value of freight transport attributes in the last mile logistics context, where limited and inflexible delivery windows together with the increase of transport flows linked to ecommerce operations make the analysis of the VOT and its reliability even more relevant.

The importance of recognizing the relationship between transit time, and the reliability of transit time has been highlighted in recent empirical studies. The importance of estimating the VOR as the level of unexpected variability in travel times also becomes

particularly relevant in the case of multimodal transport chains and the promotion of environmentally sustainable transport chains.

Taking into account the aforementioned challenges in freight transport, special attention should be paid to the effect that future technological innovations and ICT developments may have on the valuation of transit time and reliability. Digitization and automatization are two of the main disruptive innovations in the transport and logistics industry. New digital developments built on big data, cloud and connected platform technologies, blockchain, or AI will provide ease of access and transparency for the entire logistics chain, with a swift, near real-time integrated transport service. This implies greater flexibility in dealing with potential delays in delivery time and an increased ability to reduce variability in transit times. While having real-time information on unexpected delays is still negatively affecting passenger's utility, technological advances that provide this information for freight transport operators and users can have unprecedented effects in the level of industry competitiveness in the long term.

Introduction

Freight transport is a fundamental component of modern life and the world economy, increasingly influenced by globalization and e-commerce. Since cities are expected to host the majority of the world population in the next years, most of the goods will have urban settlements as final destination, with an increase of transport activities and space sharing among different components. This implies greater stress on city sustainability, in terms of negative externalities like congestion, accidents, noise, reduced quality of life, air pollution, and climate change. Besides, urban freight transport (UFT) is a complex world characterized by numerous actors with heterogeneous interests. Cities need appropriate solutions and policies to increase their sustainability and efficiency. However, policies are effective only if the impacted agents adopt them and change their behavior. As pointed out by Holguín-Veras et al. (2017a), “the lack of research on how best to influence the behaviour of the freight system and supply chains remains a formidable obstacle to the implementation of comprehensive policies to improve their overall performance.” A strong knowledge of behavioral underpinnings characterizing stakeholder choices is thus required.

Based on this premise, this paper reports on the international debate on freight behavior research by focusing on the importance of: (1) behavior change and stakeholder engagement for UFT policy-making; and (2) *ex-ante* behavioral assessments of UFT policies to guarantee their uptake and spread. New behavioral analyses are needed to complement technical analyses, by considering both solution feasibility and policy acceptability. We illustrate a procedure to perform a stakeholder behavioral analysis, based on integrated models to adequately tackle this issue. Before introducing the procedure, a literature review on behavior change and stakeholder engagement in UFT policy-making is presented.

Behavior Change and Stakeholder Engagement in UFT Policy-Making

The complexity of UFT issues implies that there are no perfect solutions, forcing policy-makers to accept compromises based on the trade-offs involved. These should be clearly identified when evaluating and selecting alternatives, representing an important and crucial phase which should not be underestimated. In this respect, policy-makers are interested in the *ex-ante* assessment of UFT solutions, which can be difficult due to the multiple interests and variety of stakeholders involved. This is even truer for innovative solutions in freight transport based on stakeholder cooperation, for example, off-hour deliveries (Gatta et al., 2019; Holguín-Veras, 2008; Marcucci and Gatta, 2017), or when promoting the sharing economy paradigm, for example, “crowdshipping” (Marcucci et al., 2017a; Punel and Stathopoulos, 2017; Simoni et al., 2019). In addition, it should be noted that policy-planning activities do not take place in a vacuum and that the only successful way to foster change is to constructively engage all stakeholders to develop consensus-based strategies. From a modeling standpoint, the individual interests and the ensuing behavioral changes that a modification of the *status quo* would most likely induce must be included in the policy-making process (Gatta et al., 2017).

Behavior change is the end goal policy-makers aim for. A recent trend to engage and promote sustainable behaviors foresees the use of game dynamics. This is usually referred to as “gamification,” that is, the use of game design elements in nongame contexts. This instrument is also gaining success in the mobility domain. In this respect, Marcucci et al. (2018) proposed an advanced user-centered approach to reliably build a user-centered gamification process applied to UFT that accounts for players’ heterogeneous preferences.

Behavioral analysis is fundamental to elicit stakeholder preferences and investigate their utility maximizing behavior. This can be performed through disaggregate behavioral freight models like discrete choice models (DCMs) (Gatta and Marcucci, 2015; Holguín-Veras and Wang, 2013; Marcucci and Gatta, 2016). Typically, preferences about hypothetical policy scenarios are elicited through stated choice experiments (SCEs), while DCMs are used to estimate the willingness to pay related to single policy components. Besides, one should not underestimate the possible policy effects arising from the dynamic interactions among agents often characterized by conflicting objectives.

Stakeholder engagement in the planning processes and a deep understanding of the behavioral aspects, intertwined with their decision-making process, are therefore crucial to define and implement effective policies, given the variety of heterogeneous UFT stakeholders with conflicting interests. However, the traditional planning approach transport planners and practitioners adopt does not consider freight a priority, focuses mainly on passengers, and is implemented within a well-established framework.

In this respect, transport planning has undergone a continuous evolution over the years, from “planning” intended as a “plan document” to a “plan process,” and from a “strongly rational” to a “cognitive rationality” approach, where the concept of choice optimization has been overcome with that of satisfying the community needs in an evolving process (Cascetta et al., 2015). However, while quantitative methods for *ex-ante* technical/economic assessments of transport policies are well established, there is still a general deficiency of methods aimed at assessing policy acceptability from a stakeholder’s point of view (Le Pira, 2018). New behavioral analyses are needed to complement the technical ones, so to identify and evaluate effective and shared policies, by considering both their feasibility and acceptability. In what follows, this paper illustrates a procedure aimed at a stakeholder behavioral analysis based on integrated models.

Stakeholder Behavioral Analysis

The important role of a behaviorally consistent and agent-specific approach in modeling UFT policy impacts on stakeholder behavior is widely recognized, even if only a limited number of papers have adopted this perspective, both for data acquisition and for model estimation (Gatta and Marcucci, 2016). The proposed stakeholder behavioral analysis is based on a well-thought-out integration of DCMs and agent-based models (ABMs). The rationale for these two approaches will be presented in the following.

Discrete Choice Models

DCMs can be quite useful in helping policy-makers devise the possible policies stakeholders accept, given their preferences for alternative configurations. One can also estimate the willingness to pay/accept for each mix of measures, providing a monetary evaluation of alternative policy components.

Data acquisition is based on SCEs (Louvière et al., 2000). Sampled stakeholders respond to a sequence of choice tasks where they can choose one policy alternative out of a numerable and finite choice set. Stakeholders’ choices are supposedly based on the perceived utility that alternative policy components have. Microeconomics assumes rational agents maximize utility, which is modeled as a random variable reflecting the assumption that the decision-maker has perfect discriminative capability while the analyst has incomplete information. Utility is composed of a deterministic and a stochastic term. Different assumptions on the distribution of the latter give rise to different DCM specifications. DCMs represent valuable instruments in: (1) addressing stakeholder preferences with respect to alternative policy configurations; (2) determining the respective substitution rates between the different, and possibly contrasting, policy components; and (3) predicting the behavior and acceptability through scenario analysis. While all these features are useful and desirable with respect to an empirically relevant and robust *ex-ante* policy evaluation, when dealing with simulations DCMs do not prove versatile in mimicking interaction effects among different stakeholders which, in reality, permeate the UFT environment. In this respect, knowing how single stakeholders would choose is not sufficient when the system outcome is highly influenced by the interactions taking place among agents. A dynamic simulation approach seems more appropriate to deal with interaction effects.

Agent-Based Models

ABMs aim at simulating a system whose main components are single agents, defined as autonomous entities capable of acting under certain behavioral rules (Macal and North, 2010). The structure of an ABM consists of: (1) a set of agents, with certain properties and behaviors; (2) a set of relationships and methods of interaction, with a topology that defines how and with whom agents interact; and (3) the agents’ environment, where agents interact with each other and with the environment itself. Agents are provided with simple behaviors linked to local information. However, when many agents are simulated as a group, emergent phenomena often arise. ABMs are widely used to represent real-world complex systems and to reproduce distributed decision-making processes as the outcome of a set of autonomous entities interacting in a common environment. Several ABMs have been implemented lately to reproduce and investigate UFT problems when explicitly considering the interaction among UFT actors (Holmgren et al., 2012; Roorda et al., 2010; van Duin et al., 2012).

However, despite the convenience and adaptability of these models, a lack of data to calibrate the models is a common problem encountered in many ABMs. In general, this induces assigning random values to the attributes, so as to study the emergence of collective phenomena in a bootstrapping fashion. In this regard, data characterizing single agents’ preferences, such as utility functions derived from SCEs, can improve the predictive capacity of the model and its forecasting reliability.

Figure 1 Decision-making model for UFT planning including stakeholder behavioral analysis. Source: *Le Pira et al., 2017*.

Stakeholder Behavioral Analysis

A combination of DCMs with ABMs has proved to be suitable for modeling stakeholder involvement in policy-making, allowing their intrinsic limits to be overcome. DCMs can provide sophisticated agent-specific data accounting for personal heterogeneity in preferences, while ABMs simulate dynamic processes and, therefore, interaction. *Marcucci et al. (2017b)* apply this integrated approach in the field of participatory UFT policy-making, by implementing an ABM based on DCM utility functions. The integrated modeling approach produces an added value for UFT policy-making. In fact, along with technical and economic analyses, the stakeholder behavioral analysis contributes both to the *ex-ante* policy assessment needed to support an effective participatory decision-making process and to help policy-makers in taking well-thought-out decisions.

Le Pira et al. (2017) adopt an integrated extension of the commonly used decision-making modeling approach, which combines: (1) a cognitive rational approach to organize the decision-making process, (2) a five-level stakeholder engagement process, and (3) quantitative analyses and methods. The stakeholder behavioral analysis can and should be considered as an additional set of activities representing the “fourth leg” of the UFT planning process (the red blocks in *Fig. 1*). The “fourth leg” introduced consists of a:

1. preliminary analysis aimed at identifying relevant UFT stakeholders and define the policy package components and elements to be used in the experimental design;
2. survey aimed at eliciting stakeholder preferences through SCEs and understanding the nature of their existing social interactions;
3. modeling and simulation phase, where DCMs are estimated and ABMs implemented accordingly, with all the acquired data and the agent-specific utility functions from DCMs; and
4. set of scenario simulations of interaction processes among stakeholders with the aim of unveiling acceptable alternative packages, using opinion dynamics mechanisms.

The technical/economic feasibility of the “most acceptable policy package” derived from the simulations has to be evaluated by quantitative methods and tools, capable of mimicking the effects of alternative transport system configurations (i.e. transportation system analysis). This should guarantee decisions that are consistent with previously identified objectives, while taking into account the heterogeneous preferences of stakeholders and behavioral aspects linked to their decision-making. This decision-making model ensures stakeholder engagement and behavioral evaluations in designing and assessing UFT solutions toward sustainability and efficiency.

Conclusion

A deep understanding of the behavioral aspects linked to stakeholder decision-making is crucial in order to define and implement effective policies, given the variety of heterogeneous UFT stakeholders with conflicting interests. Besides, behavior change forms the basis of any solution of urban freight problems. Shared and long-standing policies must account for and accommodate both private and public objectives. Therefore, urban freight policies/solutions should emerge from a collaborative/participatory approach, compatible with larger societal sustainability goals. This paper focused on the importance of stakeholder engagement and behavior change for UFT policy-making, and of an *ex-ante* behavioral assessment of UFT policies to guarantee the spreading of solutions toward efficiency and sustainability. A stakeholder behavioral analysis, based on integrated simulation/econometric models, has been presented, with the overall aim to include the heterogeneous preferences of stakeholders and their interactive behavior in the decision-making process. Any planning process oriented to sustainability should consider stakeholder-led behaviorally based evaluations as an important part of the decision-making process.

Acknowledgment

We would like to thank all those who have collaborated in the activities performed by the Transport Research Lab at Roma Tre University (TRELab—www.trelab.it) that supported most of the research that forms the basis of the present paper.

Biographies

Edoardo Marcucci is Full Professor of Transport Economics at both Molde University College and Roma Tre University, where he is codirector of *Transport Research Lab*. He is currently coeditor in Chief of Research in Transportation Economics. Being an author of several articles published in international top journals, his research interests mainly focus on urban freight distribution, stated preference, discrete choice modeling, and interaction effects in group decision-making. He has been involved in several international, national research projects, and evaluation committees.

Valerio Gatta is a Researcher of Transport Economics and codirector of *Transport Research Lab* at Roma Tre University. He has an extensive research experience in innovative transport solutions, especially in urban freight, linked to decision-making processes and sustainability, with particular reference to stated preference survey designs and discrete choice modeling techniques. Advanced methods and models for policy acceptability and behavior change analysis are at the core of his academic path.

Michela Le Pira has a PhD in transport engineering and is currently a Research fellow/lecturer specialized in Transport Planning at the University of Catania (Italy). Her PhD research focused on public participation in transport planning supported by agent-based modeling and multi-criteria decision methods. Postdoc at University of Roma Tre and at the University of Catania, she worked on participatory decision-support methods for sustainable urban freight transport policy-making. As a research fellow at the University of Catania and guest researcher at TU Delft (Netherlands), she is currently investigating new mobility services for both passengers and freight.

Container Transport by Sea: From Infancy to a Mature Business

The container liner shipping industry consists of shipping companies involved in the transportation of containerized goods over sea. Scheduled liner services are offered between ports using a fleet of owned and or chartered container ships. The ships carry containerized cargo in standardized unit loads of 20 foot long (i.e., 20 Foot Equivalent Unit or TEU) or in forty foot dry cargo containers (i.e., FEU). Occasionally, slightly diverging container units are also loaded on container vessels such as high cube containers, tank and open top containers and 45-foot containers. The launching of the first containership *Ideal X* by Malcolm McLean in 1956 is often considered as the beginning of containerization (Levinson, 2006). In the early years of container shipping, vessel capacity remained very limited in scale and geographical deployment, and the ships used were simply converted general cargo ships or tankers. Shipping companies and other logistics players hesitated to embrace the new technology, as it required large capital investments in ships, terminals, and inland transport. The first transatlantic container service between the US East Coast and Northern Europe in 1966 marked the start of long-distance containerized trade. Soon the containerization process expanded over maritime and inland freight transport systems (Rodrigue and Notteboom, 2009).

Container shipping developed rapidly due to the adoption of standard container sizes in the late 1960s and the awareness of industry players about the advantages and cost savings resulting from faster vessel turnaround times in ports, the reduction in the level of damage and associated insurance fees, and the integration with inland transport modes such as trucks, barges, and trains. The container and the associated maritime and inland transport systems proved to be very instrumental to the consecutive waves of globalization. Container shipping also became an essential driver in reshaping global supply chain practices allowing global sourcing strategies of multinational enterprises and the development of global production networks. New supply chain practices in turn increased the requirements on container shipping in terms of frequency, schedule reliability/integrity, global coverage of services, rate setting, and environmental performance.

The large-scale adoption of the container, in combination with the globalization process, drove the worldwide container port throughput from 36 million TEU in 1980 to 237 million TEU in 2000, 545 million TEU in 2010, and 771 million TEU in 2018 (figures Drewry). This figure includes full and empty containers. The world container traffic, that is the absolute number of loaded containers being carried by sea (excluding empties), has grown from 28.7 million TEU in 1990 to 152 million TEU in 2018 (figures UNCTAD). The ratio of containerized trade over container port throughput shows that a container on average is loaded or discharged multiple times between the first port of loading and the last port of discharge.

The center of gravity of the container business is shifting to Asia. During the last 20 years, the transatlantic container trade gradually lost its dominance to the transpacific and Europe-Far East trades. About 423 million TEU or 55% of the world's total port throughput in 2018 was handled by Asian container ports. The dominance of Asia is also reflected in the world container port rankings. In 2018 16 of the 20 busiest container ports came from Asia, mainly from China (Lloyd's List, 2019). In the mid-1980s there were only six Asian ports in the top 20, mainly Japanese load centers.

Demand-Supply Dynamics and the Financial Performance of Container Shipping Lines

Despite sustained growth brought by the containerization process, container carriers have always somewhat underperformed financially compared to other players in the logistics industries. Fig. 1 shows that since 2009, the container shipping industry has been struggling to achieve positive operating margins.

Figure 1 Average operating margin of main carriers by quarter, 2008–2017. Average of CMA CGM (including APL to 2Q2016), China Shipping (to 1Q2016), EMC, Hanjin (to 3Q 2017), Hapag-Lloyd (including CSAV to 2014), HMM, K-Line, Maersk Line, MOL, NYK, Wan Hai Lines, Yang Ming and Zim. *Source: Author's compilation based on data Alphaliner*

The weaker performance is linked to the combination of capital-intensive operations and high risks associated with the revenues. For most shipments, the freight rate only accounts for a very small portion of the shipment's total value, but as carriers cannot influence the size of the final market, they will try to increase their short run market share by reducing prices (Fusillo, 2006). As such, shipping lines may reduce freight rates without substantially affecting the underlying demand for container freight. The fairly inelastic nature of demand for shipping services constitutes the core problem behind the financial performance of container shipping lines. When the market is characterized by vessel oversupply, processes of rate erosion unfold as shipping lines try to increase their respective market shares by lowering the freight rates without substantially impacting the total demand. Such price competition continues till the freight rates stabilize at a low level, just above the "refusal rate," that is the lowest rate at which the shipping line prefers to operate its vessel, rather than having it in lay-up. If the freight rate on a specific route would fall below the refusal rate, then many vessels would be laid up. The resulting reduction in vessel capacity would push rates back up to a level above the refusal rate. When demand starts to pick up, ships are taken out of lay-up. The freight rates move away from the refusal rate once all vessels are out of lay-up and all deployable capacity is operational in the market. It is only then that rates start to increase significantly. Rates will reach their highest level when the utilization of the fleet reaches its upper limits and not enough new capacity is added to the market. At that moment, container shipping lines massively order new vessel capacity, leading to a shockwave of new capacity being brought into the market 1.5 to 2 years later (i.e., the time lag between vessel order and delivery), typically pushing the shipping market back into a period of overcapacity and lower rates. These dynamics in the shipping market, combined with the rather inelastic demand, force shipping lines into an intense concentration on costs and to seek negotiated long-term contracts with large shippers, with a view to securing cargo. Even though lower rates may allow carriers to take on extra cargo, in most cases where there remains capacity, it also reduces their profitability.

The combination of poorly differentiated rates (too many customers to negotiate a rate for every cargo) and inflexible capacity causes a pricing problem and explains existing freight rate volatility in the market. Shipping lines are not able to achieve rate stability as they cannot adjust vessel capacity to meet short run demand fluctuations (see later). High commercial and operational risks are associated with the deployment of a fixed fleet capacity (at least in the short run) within a fixed schedule between a set of ports of call at both ends of a trade route. Unused capacity cannot be stored and used later. Once the large and expensive container liner services are set up, the pressure is on to fill the ships with freight.

Freight Rates and Surcharges

The revenue base of container shipping lines consists of freight rates collected from the shippers or their representatives for the maritime transport of containerized cargo, and mostly complemented by a set of surcharges. All-in ocean freight rates have fluctuated significantly since 2009, as exemplified by the Shanghai Containerized Freight Index (Fig. 2) and other similar indices

Figure 2 Shanghai Containerized Freight Index—Comprehensive Index and indices for Northern Europe and the Mediterranean, August 2016–April 2019. *Source:* Author's compilation based on data www1.chineseshipping.com.cn

such as the World Container Index or the China Containerized Freight Index). Also, contract container freight rates are influenced by the balance of power between shippers and shipping lines in rate negotiations.

The freight rates can vary greatly depending on the economic characteristics (e.g., cargo availability, imbalances, competitive situation among shipping lines) and technological characteristics (e.g., maximum allowable vessel size) of the trade route concerned. The existence of large cargo imbalances on a number of trade routes has a significant impact on the pricing problem. Trade imbalances also affect shippers in their ability to access equipment. In order to guarantee space, shippers may double book their container loads, leading to missed bookings for shipping lines. Container liner companies can react by imposing surcharges in the form of a “no show” fee.

Base freight rates or freight all kinds rates are applicable in most trades. These freight rates are lump sum rates for a container on a specific origin-destination relation irrespective of its contents and irrespective of the quantity of cargo stuffed into the box by the shipper himself. On top of these base freight rates liner companies charge separately for additional items through a range of surcharges. Still, some (larger) customers receive all-in prices. The most common surcharges include fuel surcharges (Bunker Adjustment Factor or BAF, but also other terms are used), surcharges related to the exchange rate risk (Currency Adjustment Factor or CAF), port congestion surcharges, terminal handling charges (THC) and various container-equipment related surcharges (e.g. demurrage charges, detention charges, equipment handover charges, equipment imbalance surcharge, special equipment additional for open top container, heavy lift, etc.). THC are a tariff, charged by the shipping line to the shipper and which (should) cover (part or all of) the terminal handling costs, which the shipping line pays to the terminal operator (Dynamar, 2003). The THC vary per shipping line and per country and are a negotiable item for large customers. Fuel surcharges are aimed at passing (part of) the fuel costs on to the customer through variable charges (Notteboom and Cariou, 2013). In the second half of 2018, container shipping lines started to adjust fuel surcharges on a trade-by-trade basis ahead of the deadline for the introduction of the low sulfur fuel rules of the IMO (i.e., a global sulfur cap of 0.5% on ship fuel from January 2020). For example, MSC implemented a new global fuel surcharge in January 2019 to replace the earlier bunker surcharge mechanism.

Liner Service Networks

Container shipping lines have designed liner services connecting global ports on each side of the trade routes. The networks are based on traffic circulation through a network of specific hubs. However, shipping lines do not necessarily opt for the same hubs. When designing their networks, shipping lines implicitly have to make a trade-off between the requirements of the customers and operational cost considerations. Shippers demand direct services between their preferred ports of loading and discharge. Shipping lines, however, have to design their liner services and networks in order to optimize ship utilization and benefit the most from scale

economies in vessel size. Their objective is to optimize their shipping networks by rationalizing coverage of ports, shipping routes, and transit time. Shipping lines may direct flows along paths that are optimal for the system, with the lowest cost for the entire network being achieved by indirect routing via hubs and the amalgamation of flows.

Bundling is one of the key drivers of container service network dynamics. The objective of bundling within an individual liner service is to collect container cargo by calling at various ports along the route instead of focusing on an end-to-end service. Such a line bundling service is conceived as a set of x roundtrips of y vessels each with a similar calling pattern in terms of the order of port calls and time intervals (i.e., frequency) between two consecutive port calls. By the overlay of these x roundtrips, shipping lines can offer a desired calling frequency in each of the ports of call of the loop.

Most liner services are line bundling itineraries connecting between two and five ports of call scheduled in each of the main markets. The Europe–Far East trade provides a good example. Most mainline operators and alliances running services from the Far East to North Europe stick to line bundling itineraries with direct calls in 3 to 5 ports in each of the main markets.

Liner services are combined to form complex multi-layer networks (Ducruet and Notteboom, 2015). The advantages of complex bundling are higher load factors and/or the use of larger vessels in terms of TEU capacity and/or higher frequencies and/or more destinations served. For example, shipping lines bundle container cargo by combining/linking two or more liner services in specific sea–sea transshipment hubs. These transshipment hubs have a range of common characteristics in terms of nautical accessibility, proximity to main shipping lanes and ownership, in whole or in part, by carriers or multinational terminal operators. Most of these hubs are located along the global beltway or equatorial round-the-world route (i.e. the Caribbean, Southeast and East Asia, the Middle East and the Mediterranean). These nodes multiply shipping options and improve connectivity within the network. In channeling gateway/hinterland cargo and sea–sea transshipment flows through their shipping networks, container carriers aim for control over key terminals in the network.

Existing liner shipping networks feature a great diversity in types of liner services and a great complexity in the way liner services are connected to form extensive shipping networks. For example, Maersk Line, MSC, and CMA-CGM operate truly global liner service networks, with a strong presence also on secondary routes. Notwithstanding the demand pull for global services, a number of individual carriers remain regionally based. Historically, Asian carriers mainly focused on intra-Asian trade, transpacific trade and the Europe–Far East route, partly because of their huge dependence on export flows generated by the respective Asian home bases. Thus while some carriers have clearly opted for a true global coverage, others are somewhat stuck in a triad-based service network forcing them to develop a strong focus on cost bases. Alliance structures (see later) provide its members with easy access to more liner services with relatively low-cost implications and allow them to share terminals.

The Importance of Asset Management in Container (liner) Shipping

Container shipping is a very capital-intensive industry where some assets are owned and others leased/chartered (Brooks, 2000). The total slot capacity of the cellular container fleet stood at 23.06 million TEU in August 2019 (covering 5330 fully cellular ships), 9.44 million TEU in 2007, 3.09 million TEU in 1997 and 1.22 million TEU in 1987 (figures Alphaliner). Container shipping lines on average charter about half of the vessels from third ship owners. Ship chartering is a particularly common practice for mid-size ships (i.e., 1000 to 3000 TEU). Container shipping lines also face large investments in their containers. The number of containers needed to run a regular container service is about twice the joint TEU capacity of the vessels deployed in that liner service. Container shipping lines and other transport operators typically own 55% to 60% of the total global container equipment, while leasing the remainder from specialized leasing companies.

Asset management is a key component of the operational and commercial success of container shipping lines, since they are primarily asset-based. Common asset management decisions for shipping lines include the management of the equipment (e.g., ships and boxes) to reduce downtime and operating costs, to increase the useful service life and residual value of vessels, to increase equipment safety and reduce potential liabilities and to reduce costs through better capacity management (Table 1).

Table 1 Asset management domains in container shipping

Lifecycle management of ships and boxes	Purchase/ordering	Cost management	Total cost of ownership and operation
	Deployment		Ship/box finance
	Performance measurement		Depreciation/amortization Decision on flag state (ship registry)
	Maintenance		Operational, financial and fiscal accounting
	Disposal (selling on second-hand market, scrapping)		Location and modalities of ship management
Contract management	Leases/charter parties(C/P)	Risk management	Safety/security (assets, people, IT)
	Warranties		Regulatory compliance
	Service-level agreements		
	Outsourcing of services		

Source: Author's compilation

Container shipping lines are particularly challenged to develop an effective asset management program for the fleet they own or operate. Vessel lifecycle management includes the procurement, acquisition, deployment, and disposal of container vessels. Fleet capacity management is complex given the inflexible nature of vessel capacity in the short run due to fixed timetables, the seasonality effects in the shipping business and cargo imbalances on trade routes. Lines vie for market share and capacity tends to be added as additional loops (i.e., in large chunks) to already existing services. Lines incur high fixed costs in this process. For example, 10 to 11 ships are needed to operate one regular liner service on the Europe-Far East trade with each of the postPanamax container vessels having a typical newbuilding price ranging from USD 100 to 150 million depending on the unit capacity of the ship and the market situation in the shipbuilding industry at the time the vessel order is placed.

Scale Increases in Vessel Size

The growing demand for maritime container transport has been met via vessel upscaling. Since the 1990s a great deal of attention is devoted to larger and more fuel-efficient vessels (Cullinane and Khanna, 1999). The mid-1970s brought the first ships of over 2000 TEU capacity. The Panamax vessel of 4000 to 5000 TEU (i.e. maximum dimensions for transit through the old Panama Canal locks) was introduced in the early 1990s. In 1989 APL was the first shipping line to deploy a post-Panamax vessel. Maersk Line introduced the Regina Maersk (nominal capacity of 6418 TEU but “stretchable” to about 8000 TEU) in 1996. Consecutive rounds of scale increases led to the introduction of the “Emma Maersk” in 2006, a container ship which can hold more than 15,000 TEU and measures 397 m length overall, a beam of 56 m, and a commercial draft of 15.5 m. The introduction of the Triple E class (about 18,000 TEU) by Maersk Line in 2013 was followed by even bigger vessels of competing lines such as COSCO Shipping (ships of up to 21,237 TEU), CMA CGM (up to 20,954 TEU), and OOCL (units of up to 21,413 TEU). The first ULCs of 23,656 TEU have been delivered to MSC in 2019, while evergreen placed an order for six ships of almost 24,000 TEU in October 2019. According to Clarkson’s database, there were 73 ULCs of over 18,500 TEU in operation on the Asia-Europe route in early 2019. In October 2018 the average container vessel on the Asia—North Europe trade measured 14,193 TEU compared to 11,711 TEU in 2015, 9,444 TEU in 2012, 6,164 TEU in 2006 and 4,250 TEU in 2002 (data Blue Water Reporting). The introduction of ever larger container vessels has resulted in an overall upscaling across the main east-west trade routes, with big vessels also cascading to north-south routes.

However, the focus of container carriers on larger vessels did not lead to a more stable market environment. Consecutive rounds of scale enlargements in vessel size have reduced the slot costs in container trades, but carriers have not reaped the full benefits of economies of scale at sea (Lim, 1998). The large container vessels can be deployed efficiently on the major trade lanes, provided they are full. Unpredictable business cycles and the seasonality on some of the major trade lanes (e.g., the demand peak just before Chinese New Year) have more than once resulted in unstable cargo guarantees to shipping lines. Adding postPanamax capacity gave a short-term competitive edge to the early mover, putting pressure on the followers in the market to upgrade their container fleet and to avert a serious unit cost disadvantage. A boomerang effect eventually also hurt the carrier who started the vessel scaling up round.

Operational Strategies of Container Shipping Companies

The container shipping industry goes through consecutive cycles of vessel oversupply and capacity shortages. However, the periods with vessel overcapacity are generally much longer. Overcapacity situations are often sustained as a result of a vicious circle, which takes many years to dissolve. Overall, crises and overcapacity situations in the container shipping industry are partly the result of exogenous factors such as a demand drop and partly the result of endogenous factors such as wrong investment decisions by shipping lines. Much of the overcapacity problems are linked to the failure by the key stakeholders, in the first place the ship owners and providers of ship finance to correctly anticipate the future markets for different ship types and sizes. The liner shipping community creates the cyclicalities and adds significantly to the volatility of the business environment through investment and allocation decisions.

One way for shipping lines to fight overcapacity is by postponing or canceling newbuilding orders. Shipping lines can also decide to absorb overcapacity by laying up vessels. For example, in the Autumn of 2009 during the financial-economic crisis, the worldwide laid-up fleet totaled an elevated 12% of the world container fleet (figures Alphaliner). Another measure to absorb overcapacity involves the suspension of liner services. This can involve (1) a full and indefinite termination of a liner service; (2) a temporary suspension of a liner service for a couple of months; or (2) the announcement of some blank sailings to cope with a short-lived seasonal drop in demand. The latter practice is very common around the Chinese New Year period each year, given the significant drop in cargo availability to/from China around that time.

Vessel lay-ups, order cancellations and service suspensions are not the only tools used by shipping lines in an attempt to absorb overcapacity when it occurs. Many vessels are now slow steaming at around 14 to 18 knots to save on bunker costs (Ferrari et al., 2015; Notteboom and Vernimmen, 2009). The resulting longer roundtrip times help to absorb surplus capacity in the market (i.e., more vessels needed per liner service). A service speed of 14 knots or less is considered by some as the future norm for containerships, in contrast to speeds of up to 22 to 23 knots before slow steaming was introduced. Such slow steaming practices also help to reduce emissions to meet stringent MARPOL and other regulations of the International Maritime Organization (IMO). In a reaction to slow steaming and super slow steaming, shippers might have to redesign their supply chains to meet the new reality of longer transit times.

Horizontal Integration in the Container Shipping Industry

Shipping lines are viewing market mass as one of the most effective ways in coping with a trade environment that is characterized by intense pricing pressure. Trade agreements in the form of liner conferences were very common till this type of cooperation was outlawed by the European Commission in October 2008. At present, the horizontal integration dynamics in the container shipping industry are based on mergers and acquisitions (M&A) and operational cooperation in many forms ranging from slot-chartering and vessel-sharing agreements to strategic alliances. A slot chartering agreement is a contract between partners who buy and sell a defined allocation (space, weight) on a vessel in general on a "used" or "unused" basis at an agreed price and for a minimum defined period of time. A vessel sharing agreement (VSA) is established between a limited numbers of shipping companies who agree to operate a liner service along a specified route using a specified number of vessels. A VSA is usually dedicated to a certain trade route with terms and conditions specific to that route, whereas an alliance is more global in nature and could include many different trade routes usually under the same terms.

The first strategic alliances among shipping lines date back to the mid-1990s, a period that coincided with the introduction of the first 6000+ TEU vessels on the Europe-Far East trade. In 1997 about 70% of the services on the main East-West trades were supplied by the four main strategic alliances. At the time of writing, three alliances were operational in the market: 2M, Ocean Alliance and THE Alliance. The landscape looked very different compared to 2015 when four alliances were still active: 2M, Ocean Three, CKYHE and G6 (Table 2). The alliance partnerships evolved as a result of M&A and the market entry or exit of liner shipping companies (e.g., the bankruptcy of Hanjin in 2016). In recent years, even the largest shipping companies have resorted to joining alliances for their survival and in the hope of increasing margins.

The main incentives to join an alliance relate to achieving critical mass in the scale of operation, exploring new markets, enhancing global reach, improving fleet deployment, and spreading risks associated with investments in large container vessels (Ryoo and Thanopoulou, 1999; Slack et al., 2002). Strategic alliances provide its members with easy access to more loops or services with relative low cost implications and allow them to share terminals, to cooperate in many areas at sea and ashore, thereby achieving costs savings in the end.

The shipping business has also been subject to several waves of M&A. The number of acquisitions rose from three cases in 1993 to thirteen in 1998 before peaking at eighteen in 2006. The main M&A events included the merger between P&O Container Line and Nedlloyd in 1997, the merger between CMA and CGM in 1999 and the take-over by Maersk of Sea-Land in 1999 and P&O Nedlloyd in 2005. The economic crisis of late 2008 had an impact on the market structure. There was no major M&A activity in liner shipping between October 2008 and early 2014, but a new wave of acquisitions and mergers appeared inevitable in the medium term. The most recent wave in carrier consolidation started in 2014 (Crotti et al., 2019). The main recent take-overs and mergers include: the take-over of CCNI by Hamburg-Süd (2014); the merger between Hapag-Lloyd and CSAV (2014); the sale of APL container division to CMA CGM by NOL (2015); the merger between China Shipping and COSCO (2016); the merger between Hapag-Lloyd and UASC (2016); the merger of NYK line, MOL and K-Line in ONE (Ocean Network Express; 2016); the take-over of Hamburg-Süd by Maersk Line (2017) and; the take-over of OOCL by COSCO (2017).

Shipping lines opt for M&A to obtain a larger size, to secure growth, to benefit from scale advantages, and to gain instant access to markets and distribution networks. Through a series of major acquisitions (Sea-Land, P&O Nedlloyd, Safmarine, Hamburg-Süd, etc.), Maersk Line was able to maintain its position as the world's largest container shipping line and to make strategic adjustments to secure its competitive advantage on key trade routes. Fusillo (2002) argued that a large fleet capacity enabled Maersk Line to use excess capacity as a form of entry deterrence by saturating the market and reducing profit opportunities for competing carriers. In contrast to Maersk Line, MSC reached the number two position in the world ranking of container lines based on organic or internal growth. MSC was only involved in two minor take-overs such as Kenya National in 1997.

The liner shipping industry has witnessed a concentration trend in slot capacity control, mainly as a result of M&A activity. The top 20 carriers controlled 89.7% of the world's container vessel capacity in April 2019. This figure amounted to about 83% in late 2009, 56% in 1990 and only 26% in 1980 (Table 3). The top 4 companies controlled 79% of the total fleet capacity of the top 20 shipping lines in 2019, while this share was 60% in 2015 and 42% in 1995. The consolidation trend has raised concerns with respect to an overly concentrated market and the potential oligopolistic behavior of the large carriers and alliances between them. Therefore M&A activity and alliance formation in liner shipping are under scrutiny by competition authorities around the world. Alliances and carrier consolidation are having their full impact on inter-port competition given the large container volumes involved and the shift in the associated bargaining power.

Vertical Integration in the Container Shipping Industry

In response to the low margins in shipping and the demand of customers for door-to-door and one-stop shopping logistics services, shipping lines may extend the reach of their activities to other parts of the supply chain (Notteboom, 2004). Over the past decades, the largest container lines have shown a keen interest in developing dedicated terminal capacity in an effort to better control costs and operational performance, improve profitability (Cariou, 2001; Haralambides et al., 2002; Notteboom et al., 2017) and as a measure to remedy poor vessel schedule integrity (see Notteboom (2006) for a discussion on schedule unreliability). For example, Maersk Line's parent company, AP Moller-Maersk, operates a large number of container terminals through its subsidiary APM Terminals. CMA CGM, MSC, Evergreen, and Cosco are among the shipping lines fully or partly controlling terminal capacity around the world. Independent global terminal operators such as Hutchison Ports, PSA, and DP World are increasingly hedging the risks by setting up dedicated terminal joint ventures in cooperation with shipping lines and strategic alliances. Terminal operators also seek long-term contracts with shipping lines using gain sharing clauses. The above developments gave rise to a growing complexity in terminal ownership structures and partnership arrangements (Notteboom and Rodrigue, 2012).

The scope extension of a number of shipping lines goes beyond terminal operations to include inland transport and logistics. A number of shipping lines are developing door-to-door services based on the principle of carrier haulage in an attempt to get a stronger grip on the routing of inland container flows (Van Den Berg and De Langen, 2015). A number of shipping lines try to enhance network integration through structural or ad hoc coordination with independent inland transport operators and logistics service providers. They do not own inland transport equipment. Instead they attempt to use trustworthy independent inland operators' services on a (long term) contract base. Other shipping lines combine a strategy of selective investments in key supporting activities (e.g., agency services or distribution centers) with subcontracting of less critical services. With only a few exceptions (e.g., CEVA Logistics as part of CMA CGM, and Damco now fully integrated in Maersk Line), the management of pure logistics services is done by subsidiaries that share the same mother company as the shipping line, but operate independently of liner shipping

operations. A last group of shipping lines is increasingly active in the management of hinterland flows. The focus is now on the efficient synchronization of inland distribution capacities with port capacities.

Shipping lines face important challenges to further optimize inland logistics. Competition with the merchant haulage option remains fierce. The logistics requirements of customers (e.g., late bookings, peaks in equipment demand) typically lead to money-wasting peaks in inland logistics costs. Given the mounting challenges in inland logistics, shipping lines that do succeed in achieving a better management of inland logistics can secure an important cost advantage compared to rivals.

Many shipping lines are also heavily focusing on digital transformation. Through investments and initiatives in digital infrastructure and services, shipping lines are aiming for the creation of value-adding activities in the following areas:

- The optimization of operations by using data for real-time network optimization in terms of bunker savings; optimized automated vessel stowage planning; planning of container repair; and empty container repositioning; predictive maintenance of vessels and containers, etc.;
- The development of advanced commercial decision-making instruments by using data to target customers; to optimize the cargo mix within restrictions (e.g., dangerous goods); to generate transparency in the supply chains of the customers, and to develop intelligent pricing engines;
- The development of new services that can generate new revenue streams. Examples include consultancy/advisory services related to logistics chains, the aggregation and selling of trade data or the commercialization of weather data collected by vessels navigating the open seas.

Shipping lines are setting up cooperation schemes to support digital transformation processes. For example, Maersk, MSC, Hapag-Lloyd, and ONE launched a digital container platform in 2019. This Digital Container Shipping Association (DCSA) has been established with the intention of setting standards for the digitalization of container shipping to overcome the lack of a common foundation for technical interfaces and data. The neutral and nonprofit association is open to all ocean carriers who wish to join. DCSA has no intention of developing or operating any digital platform of its own. DCSA will interact with other associations and organization such as the United Nations (i.e., Rules for Electronic Data Interchange for Administration, Commerce and Transport or UN/EDIFACT), the International Organization for Standardization, the Blockchain in Transport Alliance, and OpenShipping.org, which offers an open source standard for global shipping.

The Challenges Ahead

The establishment of world-embracing container shipping networks has facilitated globalization processes and associated global production and logistics practices. Still, the financial performance of many container shipping lines remains poor. As discussed earlier, the core of the problem lies in a combination of the capital-intensive operations and high risks associated with the revenues, due to a combination of volatile markets and inflexible capacity in the short run. Shipping lines have developed a very strong focus on market shares and on the lowering of the cost base by ordering ultra large vessels and by focusing on horizontal integration. The resulting low rates and often negative margins did not make shipping lines fundamentally revise their business strategy. The increasing "commoditization" of the liner shipping market is urging shipping lines to consider other growth strategies and revenue models by focusing on supply chain integration/vertical integration and digital transformation. Thus the liner shipping industry is challenged to walk the path of breakthrough innovation in order to reinvent itself. This is a difficult task for an industry where business model changes are not drastic and tend to be implemented slowly.
